Primary cilia project from the surface of most vertebrate cells and are thought to be sensory organelles. Defects in primary cilia lead to cystic kidney disease, although the ciliary mechanisms that promote and maintain normal renal function remain incompletely understood. In this work, we generated a floxed allele of the ciliary assembly gene Ift20. Deleting this gene specifically in kidney collecting duct cells prevents cilia formation and promotes rapid postnatal cystic expansion of the kidney. Dividing collecting duct cells in early stages of cyst formation fail to properly orient their mitotic spindles along the tubule, whereas nondividing cells improperly position their centrosomes. At later stages, cells lacking cilia have increased canonical Wnt signaling and increased rates of proliferation. Thus, IFT20 functions to couple extracellular events to cell proliferation and differentiation.

Introduction

Nearly all cells in vertebrate organisms have nonmotile primary cilia projecting from the surface. In mice, severe defects in ciliary assembly cause embryonic lethality at mid-gestation, whereas milder defects lead to a syndrome of phenotypes including cystic kidney disease, liver cysts and fibrosis, polydactyly, and defects of the pancreas, brain, and eye. The primary cilia is considered to be a sensory organelle that relays information about the extracellular environment to the intracellular milieu, controlling aspects of cell physiology such as proliferation and differentiation (Satir and Christensen, 2007).

Primary cilia are evident on the epithelial cells lining kidney ducts and tubules. Ciliary defects underlie nearly all types of cystic kidney disease in humans including autosomal dominant and autosomal recessive polycystic kidney disease (PKD; Pazour, 2004). In PKD, increases in kidney tubular diameter cause enlargement of the kidneys and loss of surrounding nephrons. It is thought that increased proliferation of mutant epithelial cells (Igarashi and Somlo, 2002) along with defects in planar cell polarity play roles in the development of PKD (Simons et al., 2005; Fischer et al., 2006). The function of the primary cilium in controlling the architecture of the kidney and preventing cyst formation is not understood.

Most eukaryotic cilia and flagella are assembled and maintained by intraflagellar transport (IFT). During IFT, large protein complexes called IFT particles are transported along the ciliary microtubules under the ciliary membrane and carry precursors from the site of synthesis in the cell body to the site of ciliary assembly. The particles themselves comprise ~20 unique subunits organized into A and B complexes (Rosenbaum and Witman, 2002; Scholey, 2003). Here, we characterize the function of IFT20, a complex B subunit, by creating a floxed allele of Ift20 and deleting this gene specifically in kidney collecting duct cells. We show that IFT20 functions to couple extracellular events to cell proliferation and differentiation.
Embryonic deletion of Ift20 leads to postnatal bilateral kidney enlargement (Fig. 1, A and B). At postnatal day (p) 5, control and experimental kidneys are similar in size. By p10, Ift20 mutant kidneys are slightly enlarged, then rapidly expand to ~10 times their normal weight by p23. The enlargement is caused by cystic expansion of the collecting ducts (Fig. 1 C), such that by p23, most of the kidney is replaced by collecting duct epithelium, fluid filled cysts (Fig. 1 C), and fibrotic material (Fig. S2, available at http://www.jcb.org/cgi/content/full/jcb.200808137/DC1). Blood urea nitrogen levels are more than three times higher than normal in mutant mice, which is consistent with renal failure (Fig. 1 B). Cyst-lining cells lack primary cilia and vary in appearance between cysts (Fig. 1 D). Some cysts contain flat cells with prominent microvilli at cell borders (Fig. 1 D, middle), whereas other cysts have domed cells with

**Results and discussion**

**Deletion of IFT20 in kidney leads to cystic kidney disease**

Ift20 is required for embryonic viability (not depicted); thus, to characterize the function of IFT20 in the kidney, we created a floxed allele (Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200808137/DC1) and used HoxB7-Cre to delete IFT20 in collecting ducts. HoxB7-Cre is first expressed in the mesonephric duct on embryonic day (e) 9.5 and is strongly expressed in all ureteric bud epithelial cells by e12.5 (Yu et al., 2002). The ureteric bud gives rise to the kidney collecting duct epithelium, the Wolfian duct, and the ureteral epithelium. Thus HoxB7-Cre should delete IFT20 in the collecting ducts but not in the other segments of the uriniferous tubule.
Deletion of IFT20 affects cellular architecture and Wnt signaling

Mitotic spindles in normal kidney tubules have a stereotypical orientation, with the axis of the spindle parallel to the long axis of the tubule and the metaphase chromosomes aligned perpendicularly to the tubule. This orientation is randomized in mice with cystic kidney disease caused by defects in the transcription factor hepatocyte nuclear factor 1β (Hnf1β) or by loss of Fat4, which disrupts planar cell polarity, and is less precise in rats with defects in the ciliary/centrosomal protein fibrocystin (Fischer et al., 2006; Saburi et al., 2008) or mice with mutations in the ciliary assembly protein Kif3a (Patel et al., 2008). To test if a lack of IFT20 caused a randomization of mitotic spindle orientation, we examined collecting duct mitosis in sections of p5 kidneys. p5 is just before the time of rapid cystic expansion (Fig. 1 B) and should be the point at which spindle orientation defects would be most evident. As described, there is some tubule dilation in p5 experimental animals. We were concerned that once tubule dilation had initiated, mitotic spindle orientation could be altered as a secondary effect, so we analyzed only those tubules that were not visibly dilated. Thus, at p5, tubule diameter was similar in control and experimental mice (control = 16.4 ± 0.24 μm; experimental = 17.0 ± 0.38 μm), as was the percentage of collecting duct cells undergoing mitosis (control = 2.54 ± 0.67%; experimental = 2.58 ± 0.52%; n = 5 animals, >1,000 cortical collecting duct cells counted per animal). However, in the absence of IFT20, the normal bias toward spindle orientation being parallel to the long axis of the tubule was lost (Fig. 3 A), resulting in significantly different mitotic spindle orientations between control and experimental collecting duct cells (Fig. 3 B; P < 0.001).

To probe further how the lack of a cilium might lead to misorientation of the mitotic spindle, we examined centrosomal position. Normal kidney epithelial cells are highly polarized, with centrosomes typically located at the center of the apical end of the cell. This is typically the apex of the cell so that the cilium projects from the tip of the cell into the tubule (Fig. 4 A). Without IFT20, the centrosome is often displaced from the center of the apical surface of the cell (Fig. 4, A and B). In p5 mutants, the centrosome remains at the apical end of the cell but can be found
anywhere from the lateral junction to the center of the cell. In the highly cystic kidneys of older animals, centrosomal position varies along the apical-basal axis, often localizing near the basal surface (Fig. 4 C). The process of oriented cell division in the kidney may be analogous to what occurs in adult stem cells, which divide via oriented mitosis to maintain the stem cell niche and produce cells for differentiation. Work in *Drosophila melanogaster* stem cells indicates that centrosome dynamics underlie this process: the mother centrosome remains anchored at a fixed position in the cell and the daughter centrosome moves to a stereotypical position at the other side of the cell before the mitotic spindle is established. Mutations that disrupt the centrosomes disrupt the orientation of the mitotic spindle and lead to less-ordered cell division planes (Rebollo et al., 2007; Rusan and Peifer, 2007). If the process in kidney cells is similar to that in stem cells, thecilium may provide an external cue to position the mother centrosome, coordinating the cell division plane of an individual cell with neighboring tubular cells. In addition to mislocalized centrosomes, some cells lacking IFT20 showed centrosome overduplication or segregation defects, with large numbers of γ-tubulin-positive structures found throughout the cell (Fig. 4 C). This centrosomal amplification was not frequent, and cells with this phenotype were clustered together, which suggests that an additional mutation had occurred in a precursor cell that then gave rise to the cluster.

Mitotic spindle orientation is thought to be controlled by the noncanonical branch of the Wnt pathway, whereas the canonical branch controls gene expression through the interaction of β-catenin with T cell factor (Tcf) transcription factors (Merkel et al., 2007). Because we observed defects in mitotic spindle orientation, we sought to determine if β-catenin signaling was altered in Ift20 mutant kidneys. At p10, β-catenin staining was similar in the collecting ducts and cysts of control and experimental animals (Fig. 5 A, top). However, cysts in adult experimental mice (p33) stained more strongly for β-catenin than did control collecting ducts (Fig. 5 A, bottom). To discern cellular distribution of β-catenin, Western blots of cytosolic and nuclear kidney fractions were probed with antibodies to β-catenin and to dephosphorylated β-catenin, which is competent to enter the nucleus and interact with the Tcf transcription regulatory complex. Total β-catenin levels in the cytoplasmic fraction were slightly elevated in experimental kidneys. Transcriptionally active β-catenin was highly elevated in the nuclear fractions of the experimental kidneys and was also faintly detected in mutant but not control kidney cytoplasm (Fig. 5 B).

To determine if elevated dephosphorylated β-catenin heralded changes in Wnt pathway gene expression, we used Wnt signaling quantitative real-time PCR (qPCR) arrays to query expression levels of 84 Wnt-related genes in four individual mutant and control kidneys. Expression of a subset of these genes was altered in mutants (Table S1, available at http://www.jcb.org/cgi/content/full/jcb.200808137/DC1). Most dramatic in mutant kidneys was a >200-fold increase in *Wnt7a*, a gene not previously linked to kidney development or disease. *Wnt7a* null mice are viable but sterile because of defects in Mullerian duct development. They also display skeletal defects such as missing digits and extra ribs but have not been reported to have kidney defects (Parr and McMahon, 1995). Other Wnt ligands (*Wnt7b*, *Wnt10a*, *Wnt9a*, *Wnt6*, *Wnt4*, and *Wnt2*) were also up-regulated.

Figure 3. **Deletion of Ift20 leads to mitotic spindle misorientation in p5 collecting duct cells.** (A) In normal kidney tubules, mitotic spindles (phospho-histone H3, red) typically orient their axes (white lines) parallel to the long axis of the collecting duct (DBA, green; left panels in A, gray bars in B). The absence of IFT20 disrupts this arrangement, producing a more random orientation of mitotic spindles (right panels in A, black bars in B). Images are maximum projections of 16 confocal z images taken 0.5 μm apart. Bar, 5 μm. (B) Mitotic spindle orientation quantitation. Mitotic collecting duct cells were photographed, and the angle between the long axis of the tubule and the spindle was measured; angles were grouped into 10° bins. Bars in the inset show circular mean mitotic spindle orientation and the 95% confidence interval about the mean. ***, P < 0.001 (Kolmogorov-Smirnov test).

Figure 4. **Centrosome defects.** (A) In control p5 kidneys, centrosomes (γ-tubulin, red) are typically found at the center of the apical surface of collecting duct cells, whereas the position in experimental animals is more variable. The position was quantified by measuring the angle between a line along the basal surface of the cell and a line drawn between the centrosome and the center of the cell at the basal surface. The cell center was defined by the center of the nucleus. The bottom two panels illustrate this measurement. Images are maximum projections of four confocal z images taken 0.5 μm apart. (B) Quantification of the centrosome axis. n = 100. Error bars indicate SEM. (C) Two examples of the unusual localization of centrosomes (arrows) that can be found in highly cystic kidneys. Bars, 10 μm.
in mutant kidneys, along with Wnt-binding proteins (Frz6 and Frzb). Downstream Wnt signaling targets Myc, Jun, Tcf3, Tcf7, and Wisp1 increased, as did other genes such as RhoU and PPP2r5d. RhoU is a member of the Rho subfamily of small GTPases. Its overexpression causes disassembly of focal adhesions (Chuang et al., 2007) and causes quiescent fibroblasts to enter the cell cycle (Tao et al., 2001), phenotypes that may be important in the formation of kidney cysts. Ppp2r5d is a regulatory subunit of protein phosphatase 2, which plays a role in regulating entry into mitosis (Margolis et al., 2006).

Recent data on kidney development indicates that cilia and polycystins play vital roles in the embryonic and postnatal development of the kidney but may not be critical in the adult. The transition point for this ciliary dependence appears to occur in the p10–14 range (Piontek et al., 2007; Patel et al., 2008), which led us to ask if Wnt-related gene expression changes over this time period. We followed expression of a subset of the genes on the array, plus additional genes known to be associated with Wnt signaling, through postnatal development (p5, p10, and p15) and into early adulthood (p22–29). Consistent with a p10–14 ciliary dependence transition, expression levels of most of the interrogated genes at p5 or p10 did not differ between mutant and control kidneys, with the exception of Wnt7a, whose expression was modestly but significantly increased at p10. In contrast,
significant increases in expression of many genes, including Wnt1a, Wnt10a, Myc, RhoU, Lef1, and Ppp2r5d mRNAs, were seen in p15 mutant kidneys (Fig. 5 C). The relative differences in expression of these genes increased in young adult mice by combined up-regulation in mutant kidneys and decreased expression in controls. Axin2 and Tcf4, two genes associated with β-catenin activation, were up-regulated only in highly cystic young adult mice. In contrast, expression of HNF1α significantly decreased in young adult mutant kidney; mutations in HNF1α have been associated with some human renal malformations, although HNF1β abnormalities are more commonly linked to PKD (Malecki et al., 2005). How these changes in Wnt-related gene expression influence cyst formation warrants further study.

One functional consequence of up-regulated Wnt-β-catenin signaling is increased proliferation (Morin, 1999). As discussed, we did not observe differences in proliferation at p5, but adult cystic epithelium showed increased proliferation as measured by phospho-histone staining (control = 0.54 ± 0.12%; experimental = 3.87 ± 0.43%; n = 5 animals, >1,000 DBA-positive cortical collecting duct cells counted from each animal, P < 0.0001; unpaired t test).

In work in several model systems supports the hypothesis that cilia play a key role in cystic disease, but the nature of that role remains an open question. Cilia often serve as chemoreceptors (e.g., in olfaction). Although this is theoretically a possibility in the kidney, there is as yet no evidence to support this idea. Cilia can also serve as mechanosensors (Praterius and Spring, 2001). The observation that responses to flow are aberrant in cells lacking the polycystins has been used to argue that the cilium dynamically monitors flow through the tubule and uses this information to control tubule diameter and prevent cyst formation (Nauli et al., 2003). However, the observation that cilia are not required in adult animals (Davenport et al., 2007) and that cells lacking the transient receptor potential (Trp) channel TrpV4 do not respond to flow but that mice and fish lacking this gene do not develop cystic disease (Kottgen et al., 2008) calls into question the importance of dynamic flow detection to cystogenesis. Another possible function for the cilium is to regulate Wnt signaling. Wnt signaling is involved in early kidney development (Merkel et al., 2007), and the finding that expression of an activated, mutant form of β-catenin in kidney epithelium leads to cystic disease (Saadi-Kheddouci et al., 2001) suggested that defects in Wnt-β-catenin signaling underlie the transformation of a normal tubule into a cyst. More recent data show dysregulation of the Wnt-β-catenin signaling pathway in other models of cystic kidney disease, and it has been proposed that one of the functions of cilia is to regulate the switch between canonical and noncanonical Wnt signaling upon fluid flow through the nephron (Simons et al., 2005; Corbit et al., 2008; Marose et al., 2008). This idea is based partly on the observation that canonical Wnt signaling is high in tip cells of the invading ureteric bud that are not expected to be exposed to fluid flow, whereas it is low in trunk cells that are more likely to be exposed to flow (Simons and Walz, 2006). Our data supports a role for the cilium in regulating both the canonical and noncanonical branches of the Wnt pathway, although this regulation may be more complex than a switch between the two branches. It is more likely that the cilium provides spatial information to control noncanonical Wnt signaling at all postnatal time periods and also provides information to down-regulate canonical Wnt signaling at p15 and later.

It is possible that both canonical and noncanonical branches of Wnt signaling need to be upset for cyst formation to occur. That is, altered mitotic spindle orientation without an increase in proliferation could cause cells to divide in random planes, resulting in shorter tubules that are somewhat dilated but not greatly cystic. Conversely, increased proliferation with correct orientation of cell division could lead to longer tubules of the correct diameter. However, when altered mitotic orientation is combined with increased proliferation, dramatic cyst formation occurs.

Materials and methods

Histology

Mouse tissues for histological analysis were fixed by perfusion (>10 d of age) or immersion with either 4% paraformaldehyde [Electron Microscopy Sciences] or 2% glutaraldehyde [Electron Microscopy Sciences], plus 4% paraformaldehyde in phosphate buffered saline and then processed as described previously (Pazour et al., 2000). Alexa Fluor-labeled secondary antibodies (Invitrogen) were used to detect the primary antibodies. Primary antibodies used included acetylated tubulin (611-β-1, 1:10,000; Sigma-Aldrich), γ-tubulin (GTU88, 1:1,000; Sigma-Aldrich), smooth muscle actin (clone 1A4, 1:50,000; Sigma-Aldrich), phospho-histone H3 (1:250; Millipore), aquaporin 2 (1:500; BD Biosciences), β-catenin (1:1,000; Cell Signaling Technology), active β-catenin (clone 8E7, 1:300; Upstate Biotechnology), phospho-α-catenin (clone 1C4, 1:100; Cell Signaling Technology), RelB (N-17, 1:250; Santa Cruz Biotechnology, Inc.). FITC-conjugated DBA (1:20; Sigma-Aldrich) was added with the secondary antibodies. Trichrome blue staining was performed by using the Accustain Trichrome stain kit (Masson; Sigma-Aldrich).

Wide-field images were acquired with an Orca ER camera (Hamamatsu) on a microscope (Axiovert 200M; Carl Zeiss, Inc.) equipped with a 100× Plan-Apochromat 1.4 NA objective (Carl Zeiss, Inc., Images were captured with Openlab software (Improvement) and adjusted for contrast in Photoshop (Adobe). To compare images, photos were taken with identical conditions and manipulated equally. Confocal images were acquired with an inverted microscope (TE2000E2; Nikon) equipped with a Solomere Technology-modified spinning disk confocal scan head (CSU10; Yokogawa). z stacks were acquired at 0.5-μm intervals and converted to single planes by maximum projection with MetaMorph software (MDS Analytical Technologies). Bright-field images were acquired using a microscope (Axioskop 2 Plus) equipped with a color digital camera (AxioCam HRC) and acquisition software (Axiovision 4.0; all from Carl Zeiss, Inc.).

Gene targeting and mouse breeding

A gene targeting vector to modify the mouse Ift20 locus was developed using bacterial recombination (May et al., 2005). In brief, 7.6 kb of DNA from mouse BAC RP23-39999HS (Children’s Hospital of Oakland Research Institute) was captured into pLC3. Additional recombination steps placed LoxP sites in introns 1 and 3 and a neomycin selectable marker flanked by flipase recognition target recombination sites in intron 1. This construct was electroporated into mouse embryonic stem cell line AB2.2. Correctly targeted lines were identified by PCR and used to generate chimeric mice that were bred to produce a line carrying the ift20+ allele. F1P (Farley et al., 2000), Prm-Cre (O’Gorman et al., 1997), and Hoxb7-Cre (Yu et al., 2002) mice were obtained from the Jackson laboratory and then breded into the chimeric mice. Mice carrying the ift20+ allele were crossed to FLP mice to delete the neomycin selectable marker and create the ift20fl ox allele. These were subsequently crossed to Prm-Cre mice to delete exons 2 and 3 and create the ift20mut allele. Homozygous ift20+ and homozygous ift20mut mice are viable and fertile, and these lines are maintained as homozygotes. Homozygous ift20mut mice do not survive to birth, and this line is maintained by heterozygote crosses.

These sequence data are available from GenBank/EMBL/DDJ under the accession numbers listed. Tm, melting temperature.

Genotyping was done by PCR using the following primers as described in Fig. S1: [A] 5’-ACTCAGATGCAAGCCCTCGT-3’, [B] 5’-GCTAGCATCTGGCCTAGAAGC-3’, [C] 5’-GGGGAACCTTCTGGCACTAGGG-3’, and [D] 5’-GGAGGCGAGGTTCAGTTATGC-3’.

Mice with kidney collecting duct deletion of Ift20 were generated by crossing HoxB7-Cre, ift20+/− males to ift20+/− females. Offspring with the genotype HoxB7-Cre, ift20+/− were used as experimental animals, whereas HoxB7-Cre, ift20+/− were used as controls. Mouse work was approved by the University of Massachusetts Medical School animal use committee.

Serum chemistry
Blood urea nitrogen was analyzed by a Cobas Integra 400 Plus (Roche) at the Comparative Pathology Laboratory, Baylor College of Medicine.

Cell fractionation and protein analysis
Kidney cytoplasmic and nuclear extracts were prepared using the Cellyctic NuCLEAR Extraction kit (Sigma-Aldrich) protocol. For Western blot analysis, proteins were separated by SDS-PAGE and electrophoresis to Immobilon P (Millipore). After transfer, blots were blocked with TBST containing 5% dry milk and then incubated with primary antibodies in the same solution.

Gene expression
Individual kidneys were stored at −80°C in RNAlater (QIAGEN) until total RNA was isolated (QiaShredder columns, RNeasy kits with on-column DNA digestion; QIAGEN). RNA concentration was determined spectrophotometrically. Wnt-related gene expression was examined with the mouse Wnt signaling pathway RT-PCR profiler PCR arrays (PAMM-043C; SA-Biosciences) using cDNA (Reaction Ready First-Strand cDNA Synthesis kit; SA Biosciences) derived from four experimental and four control kidneys. Thermal cycling was performed in an ABI Prism 7500 instrument (Applied Biosystems) using 15-μl reactions containing 200 ng of first strand cDNA (SuperScript II First-Strand Synthesis System; Invitrogen), 0.5 μM forward and reverse primers, and PowerSYBR green PCR master mix (Applied Biosystems). qPCR reactions were performed in duplicate or triplicate at 50°C for 2 min, 95°C for 10 min, 40 cycles at 95°C for 15 s, and 60°C for 60 s, then dissociated to verify a single amplicon. For each gene, standard curves were generated from a 10-fold serially diluted (250 ng to 2.5 pg) pool of p22−29 ift20 null/fl ox kidney cDNA. Threshold cycle (CT) was calculated for each point, standard curves related CT to log cDNA dilution, and RNA abundance was estimated by relating sample CT to the standard curve. qPCR data were normalized to GAPDH expression. RT-qPCR information is shown in Table I.

Data analysis
Tubular diameter, mitotic index, centrosomal angles, and gene expression are presented as means ± SEM, and were compared between experimental and control mice with unpaired t tests. Differences between groups were considered statistically significant if P < 0.05. Circular mean mitotic spindle orientation and 95% confidence intervals (CI) were calculated using the von Mises distribution (Fisher, 1993), and the Kolmogorov-Smirnov two-sample test (Daniel, 1990) was used to discern significant differences.

Online supplemental material
Fig. S1 describes the construction of the ift20 mutant mouse and genotyping details. Fig. S2 illustrates fibrosis and the presence of smooth muscle actin-positive cells in the mutant kidneys. Table S1 provides the entire set of Wnt-related genes that were analyzed by PCR array. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200808137/DC1.

We thank M. Keeler and Dr. S. Jones (University of Massachusetts Medical School [UMMS] Transgenic Core Facility) for assistance with generation of ift20 alleles; Dr. P. Furciniti (UMMS Digital Imaging Core Facility) for assistance with confocal imaging; Dr. P. Odgren for use of his bright field microscope; Drs. K. McDermott, R. Davis, and C. Weston for assistance with histological analysis; and Drs. C. Mello and J. Claycomb for assistance with realtime PCR. We also thank F. Xu for technical assistance and S. Baker for statistical analysis of mitotic spindle orientation.
