In this work we provide experimental insights into the impact of plasma–molecule interactions on the target ion flux decrease during divertor detachment achieved through a core density ramp in the TCV tokamak. Our improved analysis of the hydrogen Balmer series shows that plasma–molecule processes are strongly contributing to the Balmer series intensities and substantially alter the divertor detachment particle balance. We find that Molecular Activated Recombination (MAR) ion sinks from H\(^{+}\) (and possibly H\(^{-}\)) are a factor ~5 larger than Electron–Ion Recombination (EIR) and are a significant contributor to the observed reduction in the outer divertor ion target flux. Molecular Activated Ionisation (MAI) appears to be substantial during the detachment onset, but further research is required into its magnitude given its uncertainty. Plasma–molecule interactions enhance the Balmer line series emission strongly near the target as detachment proceeds. This indicates enhancements of the Lyman series, potentially affecting power balance in the divertor. As those enhancements vary spatially in the divertor and are different for different transitions, they are expected to result in a separation of the \(L\gamma\beta\) and \(L\mu\alpha\) emission regions. This may have implications for the treatment and diagnosis of divertor opacity. The demonstrated enhancement of the Balmer series through plasma–molecule processes potentially poses a challenge to using the Balmer series for understanding and diagnosing detachment based only on atom–plasma processes.

1. Introduction

Divertor detachment is expected to be a crucial aspect for handling the power exhaust of future fusion devices, such as ITER and DEMO [2]. During detachment, a range of atomic and molecular processes result in simultaneous power, particle and momentum losses from the plasma to neutral species or to photons (e.g. radiative power loss). This results in a simultaneous reduction of the target plasma temperature (\(T_t\)) and the ion target flux (\(\Gamma_i\)). Such changes in the plasma facilitate large reductions in the target heat flux (\(q_t\)) as shown in Eq. (1) where \(\gamma\) is the sheath transmission coefficient and \(\epsilon\) is the surface recombination energy that is deposited when an H\(^{+}\) ion converts to an atom (13.6 eV) and afterwards to a molecule (+2.2 eV) [3].

\[
q_t = \frac{\Gamma_i (\gamma T_t + \epsilon)}{T_t} \tag{1}
\]

This simultaneous reduction of the ion target flux (\(\Gamma_i\)) and the target temperature requires target pressure (\(p_t\)) loss according to the sheath-target conditions (Eq. (2)). That target pressure loss can be facilitated through volumetric momentum losses [4–9] and may involve an upstream pressure loss as indicated in previous research on TCV [10].

Most experimental investigations into the impact of molecules on plasma-edge physics in tokamaks have utilised H₂ Fulcher band (590–640 nm) emission measurements [16,19] which arise from electronic excitation of H₂ due to plasma–molecule collisions (step a in Fig. 1). Those measurements directly show that the plasma is interacting with the molecules resulting in rovibronic (meaning electronically – resulting in Fulcher band emission, vibrationally – H₂(ᵣ) and rotationally) excitation [16,17,19]. That information, combined with model or simulation results, has been used in studies to infer information on reactions between the plasma and molecules [16,19].

Although it was suspected from DIII-D and JET studies [19,27] that the H₂ emission in the divertor may be enhanced by plasma–molecule interactions, the impact of excited atoms from plasma–molecule interactions on the atomic spectra has not yet been studied quantitatively in tokamak divertors.

1.1. The effect of plasma–molecule interactions on particle, energy and momentum balance

There are multiple chains of plasma–molecule reactions involving H₂, H²⁺ and H⁻ that ‘effectively’ ionise neutrals and recombine ions; a summary can be found in [1]. One example is molecular charge exchange (H₂ + H⁺ → H⁻ + H) resulting in the formation of H²⁺ which dissociatively recombines with an electron: H²⁺ + e⁻ → H + H. When comparing the inputs and outputs of those reactions, we observe that an ion was effectively recombed: Molecular Activated Recombination — MAR. Alternatively at higher temperatures, molecular reactions can activate the ionisation of a plasma neutral – Molecular Activated Ionisation – MAI.

Both plasma–molecule collisions and reactions impact the plasma power balance. Collisions between the plasma and the molecules transfer kinetic energy from the plasma to the molecular cloud [28–30]. Although emission (and thus radiation) from molecular (H₂) bands occurs, the radiative losses from such processes are experimentally estimated to be insignificant — in agreement with EDGE2D-Eirene modelling [20]. Radiative energy loss also occurs from excited atoms formed after plasma–molecule reactions [1,23,24] (step c in Fig. 1).

Plasma–molecule collisions transfer momentum from the plasma to the molecules, effectively acting as a momentum sink [14,28–31]. Apart from collisions, the molecular charge exchange reaction (H₂ + H⁺ → H²⁺ + H) also results in momentum losses [29,31].

1.2. The scope of this paper

In this work we employ a new technique [1] to experimental Balmer spectra from the TCV tokamak to extract information about plasma–molecule interactions. Our results indicate plasma–molecule interactions strongly increase hydrogenic line emission and modify particle balance significantly during detachment. MAI starts to contribute to the ion target flux at around the detachment onset. For the TCV case studied, MAR is ~5 times larger than the EIR ion sink (atomic processes). The final result is that the inclusion of plasma sources and sinks due to plasma–molecule processes significantly alters the picture of particle balance derived from plasma–atom processes alone.

The Balmer line emission enhancement during detachment attributed to plasma–molecule interactions: (1) is strongest near the target while the H₂ Fulcher emission region tracks the ionisation region; suggesting that different plasma–molecule interactions occur at different locations of the TCV divertor; (2) are indicative of increases of the Lyman series, which could potentially affect power balance in the divertor; (3) could have implications for divertor opacity effects as it can result in a spatial separation between the Lyα and Lyβ emission regions.
2. Spectral analysis techniques of inferring information on plasma–molecule interaction from the Balmer spectra

We have used the analysis technique ‘Balmer Spectroscopy of Plasma–Molecular Interactions’ (BaSPMI) [1] to investigate the spectroscopic data in this work. For simplicity we define Balmer line emission from electron-impact excitation of H and EIR of H\textsuperscript{+} as “atomic” contributions to the Balmer line emission while we define Balmer line emission arising from excited atoms after plasma interaction with H\textsubscript{2}, H\textsuperscript{3} and H\textsuperscript{+} as contributions to the line emission arising from “plasma–molecule interactions”. The total atomic line emission is then the sum of the “atomic” (H(H\textsuperscript{+}) and “plasma–molecule interaction” (H\textsubscript{2}, H\textsuperscript{3}, H\textsuperscript{+}) contributions [1]. BaSPMI uses chordal-integrated brightness measurements of H\textsubscript{α}, H\textsubscript{β}, as well as two other medium-n Balmer lines (e.g. n = 5–7) together with Stark inferred electron densities, and uses data from ADAS [32,33], YACORA (On the Web) [23,24] as well as AMJUEL [34].

The goal of BaSPMI is “to quantify the contribution of plasma–molecule interactions to the Balmer lines and use this to provide quantitative estimates of the influence of molecules on power losses, particle (ion) sources/sinks and Balmer line emission” [1]. This builds upon previous atomic analysis technique developed by the authors in [35] and works on the principle that certain plasma–molecule reactions result in excited atoms emitting atomic line emission, which is more dominant for lower-n Balmer lines (H\textsubscript{α}, H\textsubscript{β}) than higher-n ones.

The profile of the various emission contributions vary continuously along the line of sight. However, the analysis technique (see [1]) simplifies the emission profiles as a ‘dual slab’ model (with a hot and cold temperature) along the line of sight. This approach has been verified using SOLPS-ITER simulations for both TCV (density scan) and MAST-U (density and N\textsubscript{2} puffing scan) using ‘synthetic testing’. Although there is a strong spatial separation of the various emission and reaction regions in those simulations, the analysis of the chordal-integrated brightness still provides similar estimates of the chordal-integrated atomic and molecular ion sources/sinks as is obtained when summing those sources/sinks from the simulation directly along the line of sight. The ‘synthetic testing’, employed in [1], uses data tables from [25] for the H\textsubscript{2} + H\textsuperscript{+} → H\textsubscript{α} + H rate (for deuterium) and default AMJUEL data tables (proton) for other rates related to H\textsubscript{2} and H\textsuperscript{+} to post-process the SOLPS-ITER simulations to obtain the H\textsubscript{2} and H\textsuperscript{+} densities. Similar agreement between the analysis result and the result directly obtained from the simulation is obtained when either the AMJUEL base rate (proton) or the ‘remapped’ (T\textsubscript{e}/T\textsubscript{c}) AMJUEL rate (Eirene default for deuterium at the time) for H\textsubscript{2} + H\textsuperscript{+} → H\textsubscript{α} + H are used. Furthermore, the emission contributions from H\textsubscript{2} and H\textsuperscript{+} have been turned off individually in the synthetic testing in to verify that the analysis correctly identifies their presence [1].

Although the cross-sections for forming H\textsubscript{2} and H\textsuperscript{+} have strong isotope dependencies (see Section 1), BaSPMI does not use these rates [1] and instead detects the excited neutrals arising from reactions breaking down H\textsubscript{2} and H\textsuperscript{+}. However, BaSMPi does rely on population coefficients from Yacora (on the Web) [23,24] and MAR/MAI rates from AMJUEL [36], which are available for just protium. Nevertheless, the analysed discharge is a deuterium discharge. We provide the analysis in this work with this caveat and increased availability of data for deuteron would benefit this analysis [1].

Although the cross-section for dissociative attachment are thought to be strongly reduced for deuterium discharges [26], we keep the hydrogenic line emission arising from plasma interactions with H\textsuperscript{-} as a free parameter in this work. Removing that degree of freedom does not change any of the presented results beyond their uncertainty margins as the emission attributed to H\textsuperscript{-} will now be attributed to H\textsubscript{3} instead and the MAR/H\textsubscript{α} photon ratio for H\textsuperscript{-} and H\textsuperscript{α} are similar within experimental uncertainties [1]. We have bundled the contributions of H\textsubscript{2} and H\textsuperscript{+} together in terms of their Balmer line emission and MAR/MAI ion sinks/sources throughout this work as distinguishing between those two is beyond the scope of this paper.

3. Experimental results on TCV

The TCV discharge used for this study (#56567) has previously been analysed in detail from the point of view of atomic interactions only [10]. As shown in Fig. 2d, #56567 has a single null divertor shape with spectroscopy lines of sight intersecting the outer divertor leg along most of its length. #56567 is an L-mode Deuterium plasma with I\textsubscript{p} = 340kA discharge in reversed field (i.e. ion grad-B drift away from the primary x-point) without additional impurity seeding (although intrinsic carbon impurities are present and are an important power loss process [10]). This discharge has been repeated multiple times with different spectroscopy settings to obtain sufficient spectroscopic coverage for BaSPMI as well as to obtain Fulcher band measurements. The reproducibility of these discharges is adequate for this [10].

First we investigate particle balance of this discharge 2 based on a spectroscopic analysis [35] which assigns all medium-n Balmer line emission to atomic interactions only. Under TCV attached conditions we observe a linear increase of the ion target current (Fig. 2a). Such a linear increase is predicted by analytical models, due partially to the reduction of upstream temperature during the ramp of the upstream density [10]. The total ion target current, I\textsubscript{t}, rises stopping linearly at
around a Greenwald fraction of 0.33 (detachment onset) and rollover around a Greenwald fraction of 0.4. We observe that the atomic electron–ion recombination sink only becomes relevant at latest phase of the discharge (where the target temperature \( T_e \sim 1 \text{ eV} \), Fig. 2c), while the ionisation rate drops before this phase at the detachment onset (where \( T_e \sim 4 \text{ eV} \), Fig. 2c). Our atomic analysis has shown that the reduction of the ionisation source occurs as the power entering the recycling region becomes ‘limited’ to sustain sufficient ionisation - ‘power limitation’ [10], which has been theorised [11,37] and suspected from experiments previously [11,15].

A bifurcation starts to occur between the measured and estimated “atomic extrapolated” \( \text{H} \alpha \) emission at the detachment onset \((T_e \sim 4 \text{ eV} \) - Fig. 2c), Fig. 2b, and become increasingly more significant \((T_e \sim 2 \text{ eV} \) - Fig. 2c) as the divertor becomes colder. This is indicative of an additional source of \( n = 3 \) excited atoms. The ‘atomic’ \( \text{H} \alpha \) emission is based on the analysis of the medium-\( n \) Balmer lines, assuming the higher-\( n \) Balmer lines are only populated by “atomic” interactions [35].

While the expected \( \text{H}_2 \) densities from SOLPS-ITER simulations under these density/temperature conditions (e.g. detached \( T_e \sim 5 \text{ eV} \) plasma, \( n_e \sim 10^{19} \text{ m}^{-3} \)) contribute less than 1% of the measured \( \text{H} \alpha \) emission [3], plasma–molecule interactions involving \( \text{H}_2^+ \) (and possibly \( \text{H}^+ \)) could explain the additional \( \text{H} \alpha \) brightness after detachment [1]. Such plasma–molecule interactions lead to losses (sinks) for ions in the plasma through Molecular Activated Recombination (MAR). Other possible additional sources of \( n = 3 \) excited atoms, such as \( \text{Ly} \beta \) opacity and plasma–molecule interactions with hydrocarbons, are estimated to only increase the \( \text{H} \alpha \) emission by a few percent for these TCV conditions [1]. Therefore, we assume that the additional \( \text{H} \alpha \) emission is due to plasma–molecule interaction.

### 3.1. The evolution of detachment with plasma–molecule interactions

In Fig. 3 we apply the full self-consistent BaSPMI atomic and molecular spectroscopic analysis chain to identify the impact of plasma–molecule interactions on the measured Balmer lines during this discharge. Initially only electron impact excitation (of \( \text{H} \)) emission plays a role for all three Balmer lines (Fig. 3).

As the target temperature drops, first plasma–molecule interactions and later electron–ion recombination form an increasingly larger part of the Balmer line emission (Fig. 3). Near the detachment onset (Core Greenwald fraction \( n_e/n_{GW} \sim 0.43 \), the region of strong electron impact excitation ‘detaches’ from the target (see Fig. 3b–d), leaving a region where enhanced Balmer line emission from \( \text{H}_2^+ \) (and possibly \( \text{H}^+ \)) as well as EIR occur. This region expands as the divertor becomes colder, following the movement of the electron-impact excitation region. In the latest phases of the discharge (\( n_e/n_{GW} > 0.5 \)), “plasma–molecule interactions” are the dominant excitation process for \( \text{H}_n \) and \( \text{H} \beta \) near the target. For \( \text{H}_\gamma \) and \( \text{H} \delta \) (not shown), the impact of plasma–molecule interactions is significant, but most of the emission is from EIR. At this phase of the discharge, the fractions of \( \text{H}_\beta \), \( \text{H}_\gamma \) emission associated with plasma–molecule interactions (but not the actual brightnesses - see Fig. 4) are higher 25 cm above the target than near the target due to a lack of electron–ion recombination \((T_e \sim 2.5 – 4 \text{ eV})\). The fact that plasma–molecule interactions are an important excitation process for \( \text{H}_n \) and \( \text{H} \beta \) emission suggests that such interactions result in significant hydrogenic radiation and thus power balance, which will be investigated in future work.

To provide some insight into the evolution of different kinds of plasma–molecule interactions during detachment, we compare the brightness profile (line-integrated along the divertor leg and therefore also intersecting the private flux and common flux regions) of a part of the \( \text{H}_2 \) Fulcher band (600–614 nm) with that of the various \( \text{H}_2 \) excitation sources in Fig. 4. Fulcher band emission occurs when electrons have sufficient energy for plasma–molecule collisions to result in excited electronically excited molecules. A first observation is that the Fulcher emission penetrates throughout the divertor leg in the attached phase.

A second observation is that the Fulcher emission profile spatially follows the electron impact excitation (of \( \text{H} \)) emission profile and thus the ionisation profile. In contrast, the Balmer line emission from excited atoms after reactions with \( \text{H}_2^+ \) (and possibly \( \text{H}^+ \)) occurs below the Fulcher emission region and remains peaked near the target throughout the discharge; this suggests that there is a spatial and temperature ordering of the various molecular processes. Those two observations will be further discussed in Section 4.1.

### 3.2. Particle balance with plasma–molecule interactions

The evidence presented in the previous section suggests plasma–molecule interactions impact hydrogenic atomic line emission significantly. This has implications for particle balance in two ways: (1) When the hydrogenic Balmer spectra is attributed to be solely from
“atomic” interactions (as in [10]), any Balmer line emission from plasma–molecule interactions will be attributed to “atomic processes”; that ‘inflates’ the atomic ion source/sink estimates. (2) When plasma–molecule interactions contribute to, and are properly accounted for, in the Balmer line emission, that indicates the presence of an additional ion sink through Molecular Activated Recombination (MAR) and/or ion source through Molecular Activated Ionisation (MAI).

Particle balance is shown from the perspective of both atomic and plasma–molecule interactions in Fig. 5 for the discharge discussed throughout this paper. The difference in the ionisation estimate between Fig. 5 and Fig. 2 is due to the self-consistent consideration of both plasma–atom (H and H+) and plasma–molecule interactions (involving H2, H+, and H2) leading to excited atoms in Fig. 5. Both the ionisation estimates provide similar results until the detachment onset point ($n_e/n_{GW} \sim 0.43$). After the detachment onset, the estimate of ionisation including plasma–molecule interactions is reduced compared to that obtained when only plasma–atom interactions are included; the EIR ion sink estimate is unaltered.

During detachment, plasma–molecule interactions start to contribute to H2, Hδ (larger impact for lower $n \rightarrow 2$ compared to higher $n \rightarrow 2$ transitions) - see Fig. 3. Not including molecular effects leads to an underestimate of the ‘atomic’ Hδ/Hγ ratio (e.g. higher-n/lower-n ratio), which makes Balmer line emission ‘appear’ to be more excitation rather than recombination dominated [35], leading to a potentially significant ionisation overestimate. We conclude that a self-consistent consideration of plasma–atom and plasma–molecule interactions can be important for inferring information on electron impact excitation (of H) emission (and thus ionisation and radiated power from atomic excitation).

The analysis shown in Fig. 5 indicates that MAR is significant at the detached roll-over phase. The onset of MAR occurs between the onset of power limitation (detachment onset) and the onset of EIR ion sinks. The inferred magnitude of MAR for this discharge is ~5 times higher than the magnitude of EIR despite the emission of Hγ, Hδ (Fig. 3) being EIR dominated.

In this particular case, the MAR ion sink (magenta symbols in Fig. 5a) represents a significant fraction of the ion target flux (green symbols in Fig. 5a) (51 ± 15 %) and thus plays an important role in divertor particle balance.

Plasma–molecule interactions can also increase the ion target flux through MAI. The MAI rate calculated for this case is significant and starts to occur around the detachment onset. The MAI ion source in the detached phase is smaller than the MAR ion sink. These MAI estimates have larger uncertainties and are more sensitive to chordal integration effects as the MAI/Hγ photon ratio depends on the relative strength between molecular charge exchange and H2 ionisation, which is strongly temperature dependent [1]. However, the MAI outcomes are anti-correlated with the atomic ionisation and thus the sum (which has lower uncertainties) of MAI and atomic ion sources is shown in Fig. 5.

Most MAI in this case arises from H2+ ions (formed from H2 ionisation - $e^- + H_2 \rightarrow 2e^- + H_2^+$) in a fairly high temperature regime ($T_e = [4 - 9]$ eV as opposed to $T_e = [1.5 - 4]$ eV for MAR) near the electron-impact excitation and Fulcher emission regions, which will be discussed in Section 4.1.

To obtain a more quantitative comparison of the magnitude of ion losses through ion sinks, the reduction of the ion source and the reduction of the target ion flux, the ‘ion losses’ for these different processes are estimated, analogously to [10], and are shown in Fig. 5b. We observe that ion source losses start to occur around the detachment onset and increase from that point onwards. The detachment process starts with the total ion source losses (e.g. including MAI), which seems to be the strongest (together with MAR) contributor to the ion target flux drop. This is followed by MAR and ultimately EIR ion sinks. The magnitude of ion loss due to MAR and the observed ion loss at the target are similar.

The sum of the ion source and sink losses, however, exceeds the estimated ion target flux loss (Fig. 5) during detachment. This suggests the presence of an upstream ion flow towards the target ($I_p$ - Eq. (3)) during detachment and thus a loss of ‘high recycling conditions’. This contrasts previous findings [10] where only atomic reactions were considered and could arise from ionisation occurring above the spectrometer’s divertor chordal view range (Fig. 2d), which would be consistent with SOLPS-ITER simulations for TCV [38–40].

4. Discussion

4.1. The evolution of plasma–molecule collisions and reactions during detachment

In Fig. 1 we made the distinction between collisions of the plasma and H2, exciting H2+ rovibrationally and reactions between the plasma and H2+ (and possibly H+) leading to excited atoms and Balmer line emission. The results from Section 3.1 indicated that the Balmer line emission due to plasma–molecule interactions and Fulcher band emission emit at different locations and evolve differently during detachment. This suggests that there is a large volume in TCV of significant H2 density extending over a range in $T_e$. Different kinds of plasma–molecule interactions dominate at different positions in this volume.

Fulcher band emission occurs when electrons have sufficient energy to electronically excite H2 ($T_e > 4$ eV), which likely coincides with the region where H2 is both dissociated as well as ionised [19]. Therefore, Fulcher band emission should be fairly well localised around the hot part of the separatrix. It is thus surprising that Fulcher band emission occurs throughout the ionisation region given that the H2 primary source is at/near the target and mean free paths at the target in attached conditions are a few centimetres according to simulations [38]. This suggests that molecules enter the divertor leg radially throughout the
ionisation region, which could be attributed to the open, un baffled divertor structure at the time. According to our analysis, those molecules penetrating into the ionisation region are responsible for the significant levels of MAI inferred (Fig. 5). The measurement that Fulcher emission occurs along the entire divertor leg and follows the ionisation region during detachment (Fig. 4) is qualitatively consistent with estimating the Fulcher emission profile by employing synthetic diagnostics on TCV SOLPS simulations from [38].

These findings seem to be in contrast with filtered camera imaging findings in DIII-D which indicate that (1) Fulcher emission is present [19] in a thin layer close to the target; (2) the Fulcher emission region remains close towards the target during detachment. TCV has longer mean free paths for neutrals (5–10 cm) and molecules than DIII-D which could contribute to this discrepancy (due to lower electron densities, lower heating powers as well as an open divertor). We measure the ionisation front ($T_e = [4 – 6] \text{ eV}$) is lifted ~20 cm off the target during our experiment ($n_e/n_{GW} \sim 0.55$). Longer mean free paths and a larger distance between the target and ionisation front would facilitate a larger region in which plasma–molecule interactions occur. Additionally, the presence of other carbon emission lines [19] in the bandpass filter during the measurement on DIII-D could also contribute to the Fulcher emission region not detaching from the target.

In comparison to the primary location of Fulcher band emission, most Balmer line emission from $\text{H}_\alpha^+$ (and possibly $\text{H}_\alpha^-$) and thus the MAR ion sink as well as the $\text{H}_\beta^+$ (and possibly $\text{H}_\beta^-$) density, remains peaked near the target and extends up until the ionisation region. Near the target during detachment ($T_e = [1 – 3] \text{ eV}$) the electrons have insufficient energy to promote $\text{H}_2$ ionisation. However, vibrationally excited molecules still promote the formation of $\text{H}_2^+$ through molecular charge exchange. In other words, at the location where MAR occurs and most Balmer line emission due to $\text{H}_2$ chemistry is observed, vibrationally excited molecules are likely responsible for the formation of $\text{H}_2^+$ (and possibly $\text{H}_\beta^-$), whereas at the Fulcher band emission region $\text{H}_\alpha$ is electronically excited, dissociated and ionised into $\text{H}_2^+$ resulting in MAI.

If there is no longer sufficient energy ($T_e < [4 – 5] \text{ eV}$) for the impact electrons to electronically excite $\text{H}_2$, this would result in strongly reduced Fulcher band emission. Our results indeed indicate that the Fulcher band emission is particularly dim below the ionisation region where most molecules (as well as MAR) are expected to be present. This may have implications for the applicability of using only Fulcher band analysis to diagnose MAR.

Although the mean-free-paths between the target and the ionisation region for $\text{H}_2$ are fairly large in detached conditions due to the lower electron temperatures, the expected mean free paths of $\text{H}_2^+$ and $\text{H}_\alpha^+$, are much smaller. Potentially, transport of vibrationally excited molecules between the target and the ionisation front (and their interaction with the wall [16]) may play a role in achieving the higher vibrationally excited states near the target. Additionally, if electron impact collisions with $\text{H}_2$ have no longer enough energy to electronically excite $\text{H}_2$ ($T_e < [4 – 5] \text{ eV}$) a larger proportion of the energy transfer during those collisions could go into raising the vibrational levels in the electronic ground state, which is consistent with measurements and (vibrational-state resolved) simulations [17].

4.2. Evolution of hydrogenic line emission with plasma–molecule interactions and opacity

Our TCV results also indicate a spatial separation due to plasma–molecule interactions during detachment between the measured $\text{H}_\alpha$ ($\lambda_{\text{Ly}\beta} - n = 3$) and inferred (by extrapolating the individual emission processes) $\lambda_{\text{Ly}\alpha}$ emission regions as shown in Fig. 6.

Fig. 7 shows a TCV SOLPS simulation from [38], which is first post-processed to obtain Balmer line emissivities which include plasma–molecule interactions (Section 2) and further post-processed using ray-tracing to estimate where the emission gets absorbed due to opacity. This shows $\lambda_{\text{Ly}\alpha}$ and $\lambda_{\text{Ly}\beta}$ opacity is negligible on TCV (< 5%), hence we amplified the absorption in Fig. 7 for visibility. Plasma–molecule interactions enhance $\text{H}_\alpha$ predominantly near the target resulting in a spatial separation of the $\lambda_{\text{Ly}\alpha}$ and $\lambda_{\text{Ly}\beta}$ emission regions, qualitatively consistent with Fig. 6. As a result, $\lambda_{\text{Ly}\beta}$ emits in a region where opacity is (relatively) more dominant than for $\lambda_{\text{Ly}\alpha}$, due to the higher neutral densities near the target; significantly enhancing $\lambda_{\text{Ly}\beta}$ opacity.

Although photon opacity is expected to be insignificant for the TCV case studied here, opacity could play a stronger role in other devices such as JET, C-Mod and MAST-U where the photons traverse an integrated neutral density higher than $10^{19} \text{ m}^{-2}$ [27,41,42]. Post-processing MAST-U SOLPS-ITER simulations from [29] indicates significant opacity levels for $\lambda_{\text{Ly}\alpha}$ and $\lambda_{\text{Ly}\beta}$, whose emission regions are also separated resulting in a relatively higher opacity for $\lambda_{\text{Ly}\beta}$. The separation of the $\lambda_{\text{Ly}\alpha}$ and $\lambda_{\text{Ly}\beta}$ emission regions could have implications for the diagnosis and understanding of (photon) opacity as using $\lambda_{\text{Ly}\beta}$ opacity measurements to model the $\lambda_{\text{Ly}\alpha}$ opacity (or the influence of opacity on the ionisation and recombination rates) [27,41,42] requires assuming that $\lambda_{\text{Ly}\alpha}$ and $\lambda_{\text{Ly}\beta}$ emit and are opaque at the same regions along the line of sight. The development of spatially resolved $\lambda_{\text{Ly}\alpha}$, $\lambda_{\text{Ly}\beta}$ (as well as the Balmer series) diagnostics on tokamak divertors may be required.
4.3. Implications for other devices

This work highlights the importance of including plasma–molecule interactions in divertor plasma physics studies. There are several differences which could occur between these TCV results and other devices/conditions:

1. Our research shows plasma–molecule interactions affect particle balance in a specific temperature regime 1 < T< 2.5 eV - Fig. 2. If the divertor remains detached while T< 2.5 eV, plasma–molecule interactions with H\(^{+}\) (and possibly H\(^+\)) may not play a strong role. Furthermore, the importance of MAR is reduced in T< 1 eV detached conditions where 3-body recombination rises strongly and the EIR/MAR ratio is increased.

2. The transport of molecules and vibrational states in the molecular cloud may be different on TCV than other tokamaks due to differences in: (1) divertor geometry (e.g. baffled vs non-baffled, divertor chamber walls tight around the divertor leg); (2) wall material [16] (e.g. carbon vs tungsten); (3) molecular mean free paths (reduced with higher electron densities and heat fluxes). The transport of H\(_2\) to higher temperature regions (Sections 3.1 and 4.1) where MAI occurs may be related to the open TCV geometry and relatively large molecular mean free paths.

3. Higher electron densities than on TCV (n\(_e\) ∼ 10\(^{20}\) m\(^{-3}\)) could increase the EIR/MAR ratio as electron–ion recombination scales with the power 2–3 of the electron density [41,43] while the plasma–molecule processes influencing MAR and MAI increase less quickly with electron density.

4. The formation mechanisms of H\(_2^+\) and H\(^+\) are believed to be highly isotope dependent and could be different in deuterium–tritium plasmas.

Although differences may exist between TCV and conditions on other devices, experimental findings from both DIII-D [19] and JET [27] using deuterium plasmas are also suggestive of plasma–molecule interactions influencing Ha. At DIII-D [19], the measured Ha/\(H\beta\) line ratios were more than a factor 5 higher than that expected based on atomic interactions, which is in agreement with our TCV measurements.

Therefore, the importance of plasma–molecule interactions raised in this work may be generally applicable to other tokamaks with both deuterium and protium plasmas and further investigations on other devices are required.

5. Summary

In this work we have applied new spectroscopic analysis techniques developed in [1] to investigate the impact of plasma–molecule interactions on the detachment process in TCV during core density ramp discharges. Multi-step plasma–molecule interaction processes produce H\(_2^+\) (and possibly H\(^+\)) followed by the breakup of those species which leads to both Molecular Activated Recombination (MAR) as well as Molecular Activated Ionisation (MAI). Those reactions result in excited atoms, leading to enhancements of the Balmer series emission. We find that the impact of these reactions on both particle balance and the Balmer series emission is significant during detachment.

For our studied discharge, MAR results in ∼5 times more ion loss than electron–ion recombination. While MAR is concentrated in the detached region it occurs at higher temperatures (up to 2.5 eV) than for 3-body recombination (∼1 eV).

Balmer line emission attributed to H\(_2\) chemistry remains peaked at the target while H\(_2^+\) Fulcher emission ‘detaches’ from the target, following the ionization region, as detachment proceeds. This suggests that there is a spatial separation between the various plasma–molecule interactions.

The strong enhancement of Balmer line emission near the target attributed to plasma–molecule interactions indicates enhancements in the Lyman series, potentially impacting power losses. These enhancements are expected to result in a separation of the Ly\(\alpha\) and Ly\(\beta\) emission regions which would likely lead to changes of the effects and location of opacity.

It appears that attributing the enhancements to Balmer series emission during detachment just to plasma–atom interactions can lead to an inaccurate description of divertor particle balance.
