Failed attempt to disproof the Riemann Hypothesis

Marek Wolf

e-mail: mwolf@ift.uni.wroc.pl

Abstract
In this paper we are going to describe the results of the computer experiment, which in principle can rule out the Riemann Hypothesis. We use the sequence $c_k$ appearing in the Báez-Duarte criterion for the RH. Namely we calculate $c_{100000}$ with thousand digits of accuracy using two different formulas for $c_k$ with the aim to disproof the Riemann Hypothesis in the case these two numbers will differ. We found the discrepancy only on the 996 decimal place (accuracy of $10^{-996}$). The reported here experiment can be of interest for developers of Mathematica and PARI/GP.

1 Introduction

With the advent of the computers era the computing machines have been used to prove mathematical theorems. The most spectacular examples of such a use of computers were proofs of the four color theorem [2], [3] and of the Kepler conjecture about sphere packing in three-dimensional Euclidean space [12]. It seems to be not possible to use computers for the proof of the Riemann Hypothesis (RH), but refutation of it by numerical calculations seems to be plausible.

The Riemann Hypothesis says that the series

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}, \quad (s = \sigma + it, \quad \Re\{s\} > 1) \quad (1)$$

analytically continued to the complex plane in addition to trivial zeros $\zeta(-2n) = 0$ has nontrivial zeros $\zeta(\rho_l) = 0$ in the critical strip $0 < \Re\{s\} < 1$ only on the critical line: $\Re\{\rho_l\} = \frac{1}{2}$ i.e. $\rho_l = \frac{1}{2} + i\gamma_l$, see e.g. the modern guide to the RH [29]. In the
same book there is a review of failed attempts to prove RH in Chapter 8. Presently the requirement that the nontrivial zeros are simple \( \zeta'(\rho_t) \neq 0 \) is often added.

The first use of computers in connection with RH was checking by Allan Turing, whether the nontrivial zeros of \( \zeta(s) \) have indeed real part \( \frac{1}{2} \) [34]. Turing was convinced that RH is false. Let us quote the sentence from the first page of his paper: “The calculation were done in an optimistic hope that a zero would be found off the critical line”, but up to \( t = 1540 \) Turing has found that all zeros are on the critical line. The present record belongs to Xavier Gourdon [11] who has checked that all \( 10^{13} \) first zeros of the Riemann \( \zeta(s) \) lie on the critical line. Andrew Odlyzko checked that RH is true in different intervals around \( 10^{20} \) [23], \( 10^{21} \) [24], \( 10^{22} \) [27], but his aim was not verifying the RH but rather providing evidence for conjectures that relate nontrivial zeros of \( \zeta(s) \) to eigenvalues of random matrices. In fact Odlyzko has expressed the view, that off critical line zeros could be encountered at least at \( t \) of the order \( 10^{10^{10^{10}}} \), see [9, p.358]. Asked by Derbyshire “What do you think about this darn Hypothesis? Is it true, or not?” Odlyzko replied: “Either it’s true, or else it isn’t”. Also other famous mathematicians John E. Littlewood and Paul Turan have not believed RH is true.

There were several attempts to use computers to disprove some conjectures related to RH in the past. Sometimes it was sufficient to find a counterexample to the given hypothesis, sometimes the disprove was not direct. For example, the Haselgrove [13] disproved the Pólya’s Conjecture stating that the function

\[
L(x) := \sum_{n \leq x} \lambda(n) \tag{2}
\]

satisfies \( L(x) \leq 0 \) for \( x \geq 2 \), where \( \lambda(n) \) is Liouville’s function defined by

\[
\lambda(n) = (-1)^{r(n)}
\]

where \( r(n) \) is the number of, not necessarily distinct, prime factors in \( n = p_1^{r_1} \cdots p_n^{r_n} \), with multiple factors counted multiply: \( r = r_1 + \ldots + r_n \). From the truth of the Polya Conjectures the RH follows, but not the other way around. The Haselgrove proof was indirect, and in 1960 Lehman [16] has found on the computer explicit counterexample: \( L(906180359) = 1 \).

The next example is provided by the Mertens conjecture. Let \( M(x) \) denote the Mertens function defined by

\[
M(x) = \sum_{n < x} \mu(n), \tag{3}
\]

where \( \mu(n) \) is the Möbius function

\[
\mu(n) = \begin{cases} 
1 & \text{for } n = 1 \\
0 & \text{when } p^2 \mid n \\
(-1)^r & \text{when } n = p_1 p_2 \ldots p_r
\end{cases}
\]

From

\[
|M(x)| < x^{\frac{1}{2}} \tag{4}
\]
again the RH would follow. However in 1985 A. Odlyzko and H. te Riele \cite{28} disproved the Mertens conjecture, again not directly, but later it was shown by J. Pintz \cite{30} that the first counterexample appears below $\exp(3.21 \times 10^{64})$. The upper bound has since been lowered to $\exp(1.59 \times 10^{40})$ \cite{14}.

Especially interesting is the value of the de Bruijn-Newman constant $\Lambda$, see e.g. §2.32 (pp. 203-205) in \cite{10}. Unconditionally $\Lambda \leq 1/2$ and the Riemann Hypothesis is equivalent to the inequality $\Lambda \leq 0$. The fascinating run for the best lower bound on $\Lambda$ ended with the value $\Lambda > -2.7 \times 10^{-9}$ obtained by Odlyzko \cite{26}. Such a narrow gap for values of $\Lambda$ being compatible with RH allowed Odlyzko to make the remark: “the Riemann Hypothesis, if true, is just barely true”.

In 1997 Xian-Jin Li proved \cite{17}, that Riemann Hypothesis is true iff the sequence:

$$\lambda_n = \left. \frac{1}{(n-1)!} \frac{d^n}{ds^n} (s^{n-1} \log \xi(s)) \right|_{s=1}$$

where

$$\xi(s) = \frac{1}{2} s(s-1) \Gamma \left( \frac{s}{2} \right) \zeta(s)$$

does fulfill:

$$\lambda_n \geq 0 \quad \text{for} \quad n = 1, 2, \ldots \quad (5)$$

The explicit expression has the form:

$$\lambda_n = \sum_{\rho} (1 - (1 - 1/\rho)^n). \quad (6)$$

K. Maśliński \cite{21}, \cite{20} has performed extensive computer calculations of these constants confirming \cite{5}.

Let us mention also the elementary Lagarias criterion \cite{15}: to disprove the RH it suffices to find one $n$ that has so many divisors, that:

$$\sum_{d|n} d > H_n + \exp(H_n) \log(H_n). \quad (7)$$

The Lagarias criterion is not well suited for computer verification (it is not an easy task to calculate $H_n$ for $n \sim 10^{100000}$ with sufficient accuracy) and in \cite{7} Keith Briggs has undertaken instead the verification of the Robin \cite{31} criterion for RH:

$$\text{RH} \iff \sum_{d|n} d < e^{\gamma} n \log \log(n) \quad \text{for} \quad n > 5040 \quad (8)$$

For appropriately chosen $n$ Briggs obtained for the difference between r.h.s. and l.h.s. of the above inequality value as small as $e^{-13} \approx 2.2 \times 10^{-6}$, hence again RH is very close to be violated.

In this paper we are going to propose a method which in principle can provide a refutation of the RH. The idea is to calculate some number with very high accuracy
(one thousand digits) in two ways: one without any knowledge on the zeros of \( \zeta(s) \)
and second using the explicit formula involving all \( \rho_l \). Despite some estimation
presented in Sect.3 indicating that the discrepancy could be found merely at much
higher than a thousand decimal place we performed the calculations in an optimistic
hope that we will find the discrepancy between these two numbers, paraphrasing
the sentence of Turing. There is a lot of number theoretic functions defined often in
an elementary way being expressed also by the “explicit” formulas in terms of zeros
of the \( \zeta(s) \) function. Let us mention here the Chebyshev function

\[
\psi(x) = \sum_{n<x} \Lambda(n) \quad (= \log(\text{lcm}(2, 3, \ldots \lfloor x \rfloor))),
\]

where von Mangoldt function \( \Lambda(n) \) is defined as

\[
\Lambda(n) = \begin{cases} 
\log p & \text{for } n = p^m \\
0 & \text{in other cases}
\end{cases}
\]

The explicit formula reads, see eg. [33]:

\[
\psi(x) = x - \frac{\zeta'(0)}{\zeta(0)} - \sum_{\text{all zeros } \rho_l} \frac{x^{\rho_l}}{\rho_l} = x - \log(2\pi) - \frac{1}{2} \log \left( 1 - \frac{1}{x^2} \right) - \sum_{\text{nontr. zeros } \rho_l} \frac{x^{\rho_l}}{\rho_l} \tag{9}
\]

Also the Mertens’s function has the explicit representation (last term is comprising
contribution from all trivial zeros) [33]:

\[
\sum_{n<x} \mu(n) = \sum_{\text{nontr. zeros } \rho_l} \frac{x^{\rho_l}}{\rho_l \zeta'(\rho_l)} - 2 - \sum_{n=1}^{\infty} (-1)^n \left( \frac{2\pi}{x} \right)^{2n} \frac{1}{(2n)!(2n+1)} \tag{10}
\]

The problem with these series is they are extremely slow to converge because the
partial sums oscillate with amplitudes diminishing at very slow rates. For example
\( \psi(1000001) = 999586.597 \ldots \), while from (9) summing over 5,549,728 zeros gives
999587.15 \ldots , thus relative error is 0.000055.

In the computer experiment reported here we were able to get discrepancy less
than \( 10^{-996} \) between quantity calculated from generic formula and from explicit one
summed over only 2600 nontrivial zeros computed with 1000 significant digits.

2 The Báez-Duarte criterion for the Riemann Hypothesis

We begin by recalling the following representation of the \( \zeta(s) \) function valid on the
whole complex plane without \( s = 1 \) found by Krzysztof Maślanka [19]:

\[
\zeta(s) = \frac{1}{s-1} \sum_{k=0}^{\infty} \frac{\Gamma \left( k + 1 - \frac{s}{2} \right)}{\Gamma \left( 1 - \frac{s}{2} \right)} \frac{A_k}{k!} \tag{11}
\]
where
\[ A_k := \sum_{j=0}^{k} (-1)^j \binom{k}{j} (2j + 1) \zeta(2j + 2) \equiv \sum_{j=0}^{k} \binom{k}{j} \frac{\pi^{2j+2}}{(2j)\left(\frac{1}{2}\right)^j} B_{2j+2}. \] (12)

The expansion (11) provides an example of the analytical continuation of (1) to the whole complex plane except \( s = 1 \). Since \( A_k \) tend to zero fast as \( k \to \infty \) the expansion (11) converges uniformly on the whole complex plane \( [4] \). Based on the representation (11) Luis Báez-Duarte in \([5]\) has proved that RH is equivalent to the statement that
\[ c_k = O\left(k^{-3/4+\varepsilon}\right), \quad \forall \varepsilon > 0 \] (13)

where
\[ c_k = \sum_{j=0}^{k} (-1)^j \binom{k}{j} \frac{1}{\zeta(2j + 2)}. \] (14)

If additionally
\[ c_k = O\left(k^{-3/4}\right) \] (15)

then all zeros of \( \zeta(s) \) are simple. Báez-Duarte has shown unconditionally (regardless of validity of the RH) slower decrease \( c_k = O(k^{-1/2}) \). The plot of \( c_k \) for \( k = 1, 2, \ldots, 100000 \) is presented in the Fig.1.

The explicit formula expressing the Báez-Duarte sequence \( c_k \) directly in terms of the zeros of \( \zeta(s) \) can be written as a sum of two parts: quickly decreasing with \( k \) trend \( \bar{c}_k \) arising from trivial zeros of \( \zeta(s) \) and oscillations \( \tilde{c}_k \) involving complex nontrivial zeros:
\[ c_k = \bar{c}_k + \tilde{c}_k \] (16)

Because the derivatives \( \zeta'(-2n) \) at trivial zeros are known analytically:
\[ \zeta'(-2n) = \frac{(-1)^n \zeta(2n+1)(2n)!}{2^{2n+1}\pi^{2n}}. \] (17)

Maślanka in \([18]\) was able to give the closed expression for trend stemming from zeros \( \rho_n = -2n \):
\[ \bar{c}_k = -\frac{1}{(2\pi)^2} \sum_{2}^{\infty} \frac{\Gamma(k + 1)\Gamma(m)}{\Gamma(k + m + 1)\Gamma(2m - 1)} \frac{(-1)^m(2\pi)^{2m}}{\zeta(2m - 1)} \] (18)

Báez-Duarte is skipping the trend \( \bar{c}_k \) remarking only that it is of the order \( o(1) \) (Remark 1.6 in \([5]\)). It is an easy calculation to show (see \([36]\)), that for large \( k \)
\[ \bar{c}_k = -\frac{(2\pi)^2}{2\zeta(3)} \frac{1}{k^2} + O(k^{-3}), \] (19)

thus the dependence \( c_k = O(k^{-3/4}) \) in \([13]\) is linked to the oscillating part \( \tilde{c}_k \).
Fig. 1 The plot of the Báez-Duarte sequence $c_k$ for $k \in (1, 10^6)$. The equation for envelope was obtained from the explicit equation (27): for large $k$ the oscillating part $\tilde{c}_k$ is dominant and for $k > 100000$ $c_k$ fits well between the red lines, for details see [36].

For $\tilde{c}_k$ Báez-Duarte gives the formula [5]:

$$\tilde{c}_{k-1} = \frac{1}{2k} \sum_{\rho_l} \text{Res} \left( \frac{1}{\zeta'(s)P_k(s/2)}; s = \rho_l \right),$$

(20)

where

$$P_k(s) := \prod_{r=1}^{k} \left(1 - \frac{s}{r}\right)$$

(21)

is the Pochhammer symbol. Assuming zeros of $\zeta(s)$ are simple we can write:

$$\tilde{c}_{k-1} = \frac{1}{2k} \sum_{\rho_l} \frac{1}{\zeta'(\rho_l)P_k(\rho_l/2)}.$$  

(22)

An appropriate order of summation over nontrivial zeros is assumed in [20] and [22], see [5] Theorem 1.5. Because

$$P_k(s) = \frac{(-1)^k\Gamma(s)}{\Gamma(k + 1)\Gamma(s - k)}$$

(23)
collecting in pairs $\rho_l$ and $\overline{\rho}$ we can convert (22) to the form:

$$\tilde{c}_k = (-1)^{k+1} \Re \left( \sum_{\rho_l, \Im(\rho_l) > 0} \frac{\Gamma(k+1)\Gamma(\frac{\rho_l}{2} - k - 1)}{\Gamma(\frac{\rho_l}{2}) \zeta'(\rho_l)} \right).$$  (24)

We have found that the numerical calculation of $P_k(\rho_l/2)$ in PARI/GP directly from above product (21) is much slower than the use of the $\Gamma(z)$ functions (23).

Báez-Duarte proves in [5, Lemma 2.2] that

$$\lim_{k \to \infty} P_k(s)k^s = \frac{1}{\Gamma(1 - s)} \quad (25)$$

thus for large $k$ we can replace $k + 1$ by $k$ and transform (22) in the following way:

$$\tilde{c}_k = \frac{1}{2k} \sum_{\rho_l} \frac{k^{\rho_l/2}}{\zeta'(\rho_l)P_k(\rho_l/2)k^{\rho_l/2}} = \Re \left( \sum_{\Im(\rho_l) > 0} \frac{k^{\rho_l/2-1} \Gamma(1 - \frac{\rho_l}{2})}{\zeta'(\rho_l)} \right). \quad (26)$$

Now we assume the RH: $\rho_l = \frac{1}{2} + i\gamma_l$. Then we get for $\tilde{c}_k$ the overall factor $k^{-3/4}$ — the dependence following from RH, see (13) — multiplied by oscillating terms:

$$\tilde{c}_k = \frac{1}{k^{3/4}} \Re \left( \sum_{\gamma_l > 0} \frac{k^{i\gamma_l/2} \Gamma(\frac{3}{4} - \frac{i}{2} \gamma_l)}{\zeta'(\frac{1}{2} + i\gamma_l)} \right). \quad (27)$$

Using the formula (6.1.45) from [1]:

$$\lim_{|y| \to \infty} \frac{1}{\sqrt{2\pi}} |\Gamma(x + iy)|e^{\frac{1}{2} \pi |y|^2} |y|^{1-x} = 1 \quad (28)$$

assuming RH we obtain for large $\gamma_l > 0$:

$$\left| \Gamma \left( \frac{3}{4} + i\frac{\gamma_l}{2} \right) \right| \approx \sqrt{2\pi} e^{-\pi \gamma_l/4} \left( \frac{\gamma_l}{2} \right)^{\frac{1}{4}}, \quad (29)$$

hence we get exponential decrease of summands in the sum (27) over nontrivial zeros giving $\tilde{c}_k$ and (27) is very fast convergent. Because of that if RH is true the sum (27) will be dominated by first zero $\gamma_1 = 14.13472514\ldots$ what leads to the approximate expression (for details see [36]):

$$\tilde{c}_k = \frac{A}{k^{3/4}} \sin \left( \phi - \frac{1}{2} \gamma_1 \log(k) \right) \quad A = 7.775062\ldots \times 10^{-5}, \quad \phi = 2.592433\ldots. \quad (30)$$

For large $k$ the above formula (30) gives very fast method of calculating quite accurate values of $c_k$, orders faster than (14).

In the following we will denote by $c^g_k$ the values of the Báez-Duarte sequence obtained from the generic formula (14) and by $c^e_k$ the values obtained from explicit formula (16), i.e. in fact from (18) and (27) as no one zero off critical line is known.
3 The scenario of violation of the Riemann Hypothesis

The condition \[ \frac{1}{\zeta'(\rho_l)} = \mathcal{O}(\rho_l^\nu) , \quad \text{where} \quad 0 < \nu < 1. \] (31)

Some rigorous theorems about the possible large and small values of \( \zeta'(\rho_l) \) proved under the assumption of RH can be found in [22]. We have checked, that for first 5549728 nontrivial zeros of \( \zeta'(\rho_l) \) the largest derivative was 9.38127677 at \( \gamma = 5376610 \) and the smallest was 0.001028760514 at \( \gamma = 1773 \).

Let us suppose there are some zeros of \( \zeta(s) \) off critical line. Next let us assume that we can split the sum over zeros \( \rho_l \) in (26) in two parts: one over zeros on critical line and second over zeros off critical line. The second sum should violate the overall term \( k^{-3/4} \) present in the first sum. Let \( \rho_l^{(o)} \) denote the zeros lying off critical line (“o” stands for “off”): \( \rho_l^{(o)} = \frac{1}{2} \pm \delta_i + i \gamma_l^{(o)} \), \( \delta_i > 0 \) (as it is well known the nontrivial zeros are symmetric with respect to the critical line zero hence the combination \( \pm \delta_i \) plus there are appropriate conjugate zeros below real axis). In the factor \( |\Gamma(1 - \frac{\nu}{2})| \) the off-critical line zeros will lead only to the change of \( \gamma_l^{1/2} \) in (29) and in view of exponential decrease present in (29) the possible violation of RH in (26) will manifest through the terms \( k^{\frac{\nu}{2} - 1} = k^{-\frac{3}{4} \pm \delta_i/2 + i \gamma_l^{(o)}/2} \). The combination \( 1/k^{\frac{3}{4} - \delta_i/2} \) poses no problem as it leads to faster than required in (15) decrease of some of terms in the sum for \( c_k \). But the combination \( 1/k^{\frac{3}{4} - \delta_i/2} \) leads to violation of (15) and we want to elucidate how it can be detected. Say we want to compare \( c_k^{o} \) with \( c_k^{e} \) with accuracy \( \epsilon \), where we are interested in values of \( \epsilon \) of the order \( \epsilon = 10^{-10}...0 \). The expression for \( c_k^{o} \) is a finite sum and we can in principle calculate its value in PARI with practically arbitrary exactness (however for really large \( k \) it can take years of CPU time). Although \( c_k^{o} \) contains information coming from all zeros, to see influence of the first off critical line zero the value of sufficiently large \( k \) has to be examined. The sum for \( c_k^{e} \) is infinite and we expect that to get accuracy \( \epsilon \) we have to sum in (27) up to \( l = L \) given by (as we skip \( |\gamma_l|^{1/4} \) we will skip also \( \pi/4 \) as our
consideration are not rigorous in general):

\[ \epsilon \approx e^{-\gamma_L}, \quad \text{hence} \quad \gamma_L \approx -\log(\epsilon). \quad (32) \]

Because values of the imaginary parts \( \gamma_{l(o)} \) of the hypothetical zeros off critical line should be extremely large, perhaps even as large as \( 10^{10000} \), we suppose that \( \gamma_L < \gamma_{l(o)} \). The contribution of \( \gamma_{l(o)} \) is present in \( c^q_k \), but will not be present in the explicit sum for \( c^e_k \) cut at \( L \). To detect discrepancy between \( c^q_k \) and \( c^e_k \) larger than assumed accuracy \( \epsilon \) sufficiently large value of \( k = K \) is needed. The point is that \( k^{3/4}c^q_k \) will escape outside the strip \( \pm C \) for sufficiently large \( k = K \) and the value of such \( K \) we can estimate analyzing the explicit formula for \( c_k \).

We can estimate value of the index \( K \) from the requirement that the term \( K^{\delta_l/2} (K^{-3/4} \) is present in front of the sum for \( c_k \) \) will defeat the smallness of the term \( \Gamma(3/4 - \gamma_{l(o)}/2) \) and together their product will overcame the first summand in (26) corresponding to \( \gamma_1 \). In other words in the series (26) all terms up to \( \gamma_{l(o)} \) monotonically and fast decrease but the terms corresponding to zeros off critical line can be made arbitrary large for sufficiently large \( k \). The condition for such a \( K \) is roughly:

\[ K^{\delta_l/2} e^{-\gamma_{l(o)}} > C \quad \text{thus} \quad K > C' e^{2\gamma_{l(o)}/\delta_l}. \quad (33) \]

Because \( \delta_l \) can be arbitrarily close to zero and, as we expect, \( \gamma_{l(o)} \) is very large the value of \( K \) will be extremely huge — larger than famous Skewes number and will look something like \( 10^{10^{10}} \). Thus it is practically impossible to disproof RH by comparing \( c^q_k \) and \( c^e_k \). Mašlanka has given in [18] discussion of possible violation of (15) and he also came to the pessimistic conclusion that disproving RH by comparing \( c^q_k \) and \( c^e_k \) is “far beyond any numerical capabilities”, see pp. 7-8. We wanted to find agreement between \( c^q_{100000} \) and \( c^e_{100000} \) within one thousand digits and to our surprise the first attempt to calculate \( c^q_{100000} \) resulted in the difference already on the 87 place. We started to struggle with numerical problems to improve the accuracy and finally we got 996 digits of \( c^q_{100000} \) and \( c^e_{100000} \) the same.

4 The computer experiment

The idea of the experiment is to calculate to high precision the values of \( c^q_{100000} \) and \( c^e_{100000} \) and try to find discrepancy between them. We calculated one value \( c^q_{100000} \) from the generic formula (14), which contains contribution from all zeros of \( \zeta(s) \), even hypothetical zeros with \( \Re(\rho_l) \neq \frac{1}{2} \). Because \( \zeta(2n) \) very quickly tend 1 to get the firm value of \( c_k \) it is necessary to perform calculations with many digits accuracy. Additional problem is fast growing of binomial symbols. We performed calculation of \( c^q_{100000} \) using the free package PARI/GP [32]. This package allows to perform very fast computations practically of arbitrary precision. We have set precision to 100000 decimals and below in Table I are the partial sums of (14) recorded after summation of 10000, 20000, ... 100001 terms. In the middle of computations the partial sums
for \( c^g_{100000} \) were of the order \( 10^{30000} \) to drop finally to \( 1.609757993 \ldots \times 10^{-9} \) after summing up all 100001 terms. Separately we have repeated this calculations with precision set to 150000 places and we found the difference only from the 69900 place. Because the sum (14) is finite we got accurate say 50000 digits from this generic formula for \( c^g_{100000} \). This was an easy part, which took approximately 14 hours for precision 100000 decimals and almost 20 hours for precision 150000 digits on the AMD Opteron 2.6 GHz 64 bits processor.

### Table I

| \( n \)  | \( \sum_{j=0}^{n} (-1)^j \binom{100000}{j} \frac{1}{\zeta(2j+2)} \) |
|---------|--------------------------------------------------|
| 10000   | 5.65168726144550 \( \times 10^{14115} \)         |
| 20000   | 4.00927204946289 \( \times 10^{221729} \)       |
| 30000   | 6.08771775660800 \( \times 10^{156526} \)       |
| 40000   | 5.17938759373151 \( \times 10^{292225} \)       |
| 50000   | 1.26030418446100 \( \times 10^{30100} \)        |
| 60000   | 3.45292506248767 \( \times 10^{292225} \)       |
| 70000   | 2.60902189568574 \( \times 10^{292225} \)       |
| 80000   | 1.00231801236572 \( \times 10^{21729} \)        |
| 90000   | 6.27965251271723 \( \times 10^{14114} \)        |
| 100000  | 1.60975799392038 \( \times 10^{-9} \)           |

Now we turn to the calculation of \( c^e_{100000} \) from the explicit formulas (18) and (27), which are infinite sums. It is important not to make the replacement \( k+1 \rightarrow k \) even for \( k = 100000 \) if we want to get accuracy of the order of 1000 digits. The series in (18) decreases very fast to zero and it is very easy to get arbitrary number of digits of \( \bar{c}_k \) using the PARI/GP procedure \texttt{sumalt}.

Next we want to calculate \( \tilde{c}_k \) from (27) with 1000 digits accuracy. From \( e^{-\pi n/4} = 10^{-1000} \) we get \( \gamma_l \approx 2931.7 \) and a glance at the list of zeros of \( \zeta(s) \) (e.g. [25]) gives \( l = 2402 \) because \( \gamma_{2402} = 2931.0691 \ldots \). First 100 zeros of \( \zeta(s) \) accurate to over 1000 decimal places we have taken from [25]. Next 2500 zeros of \( \zeta(s) \) and derivatives \( \zeta'(\rho_l) \) with precision 1000 digits we decided to calculate using the built in Mathematica v.7 procedures \texttt{ZetaZero[m]} and numerical differentiation \texttt{ND[...]}.. After a few days we got the values of \( \gamma_l \) and \( \zeta'(\rho_l) \). We have checked using PARI/GP that these zeros were accurate within at least 996 places in the sense that in the worst case \(|\zeta'(\rho_l)| < 10^{-996} \), \( l = 1, 2, \ldots, 2600 \). The formulas (27) and (18) were implemented in PARI with precision set to 1000 digits and to our surprise we obtained that the values of \( c^g_{100000} \) and \( c^e_{100000} \) coincide only up to 87 place:

\[
10^{-86} > \left| \frac{c^g_{100000}}{c^e_{100000}} - 1 \right| > 10^{-87}.
\]

(34)
The arguments given earlier in Sect. 3 suggested that no discrepancy should be found between $c^g_k$ and $c^e_k$ for $k = 100000$ hence we have paid attention to the numerical inaccuracies in the computation of the derivative $\zeta'(\rho_l)$ as a possible explanation. We have played with different options 20, 30, 40 terms and WorkingPrecision in ND[...], but finally we got only the moderate improvement: the difference between $c^g_{100000}$ and $c^e_{100000}$ shifted to 105 place:

$$10^{-105} < \left| \frac{c^g_{100000}}{c^e_{100000}} - 1 \right| < 10^{-104}. \quad (35)$$

Because in (27) gamma functions can be calculated in PARI with practically arbitrary digits of accuracy the only way to improve accuracy of calculation of $c^e_{100000}$ is to find a reliable method of calculating $\zeta'(s)$ with certainty that say all 1000 digits are correct. From (1) it is easy to obtain the modified expression for zeta:

$$\zeta(s) = \frac{1}{1 - 2^{1-s}} \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n^s}. \quad (36)$$

This series is absolutely convergent for $\Re(s) = \sigma > 0$ and can be differentiated term by term:

$$\zeta'(s) = -\frac{\log(2)2^{1-s}}{(1 - 2^{1-s})^2} \sum_{n=1}^{\infty} \frac{(-1)^{n-1}}{n^s} + \frac{1}{1 - 2^{1-s}} \sum_{n=1}^{\infty} \frac{(-1)^n \log(n)}{n^s}. \quad (37)$$

PARI contains the numerical routine sumalt for summing infinite alternating series in which extremely efficient algorithm of Cohen, Villegas and Zagier [8] is implemented. As this authors points out on p. 6 their algorithm works even for series like (36) with $s$ complex — (36) is alternating only when $s \in \mathbb{R}$. We have used this routine sumalt outside scope of its applicability with success to calculate $\zeta'(\rho_l)$ from (37) with precision set to 1000 digits and then calculated $c^e_{100000}$ from (27) and (18). The result was astonishing: the difference between $c^e_{100000}$ and $c^g_{100000}$ appeared on the 625 place:

$$10^{-625} < \left| \frac{c^g_{100000}}{c^e_{100000}} - 1 \right| < 10^{-624}. \quad (38)$$

Because we expect possible violation of RH should manifest at much larger $k$ we were looking for the way to still improve the accuracy of $\zeta'(\rho_l)$. We decided to make a frenzy think: we calculated again $\zeta'(\rho_l)$ using sumalt with zeros having 1000 digits but this time with precision set to 2000 (however values of $\zeta'(\rho_l)$ were stored only with 1000 digits). Thus the aim was to enlarge the number of terms summed in (37), or in fact the number of iteration performed inside sumalt until the prescribed accuracy is attained. After 18 hours on AMD Opteron 2.6 GHz we got the results. And now bingo! The first 996 digits of $c^g_{100000}$ and $c^e_{100000}$ where the same:

$$10^{-996} < \left| \frac{c^g_{100000}}{c^e_{100000}} - 1 \right| < 10^{-995}. \quad (39)$$
Fig. 2 The plot of $y(n)$ for $e_{100000}^c$ obtained by three methods. The plot (a) is the best result obtained with Mathematica with the procedure ND[... ] with the option terms=30 and WorkingPrecision=1000. The accuracy was 105 digits and the curve (a) departs from the red line at the zero $\gamma_{149} = 317.73480594237...$ for which $\exp(-\pi \gamma_{149}/4) = 4.193107483 \times 10^{-109}$. The plot (b) was obtained with PARI from the formula (37) using the procedure sumalt with precision set to 1000 digits. The $y(n)$ reaches plateau $0.0006856926750...$ at zero $\gamma_{1412} = 1884.00577834967...$, for which $\exp(-\pi \gamma_{1412}/4) = 2.391868726 \times 10^{-643}$. The curve (c) is the same as (b) but derivatives $\zeta'(\frac{1}{2} + i\gamma_l)$ were calculated with sumalt and precision set to 2000 digits. Curve (c) reaches the plateau $0.00043191361...$ at the zero $\gamma_{2430} = 2960.033617812...$ for which $\exp(-\pi \gamma_{2430}/4) = 2.298783954 \times 10^{-1010}$. 
Because we got the precision (39) it is a posteriori proof that 1000 digits of derivatives $\zeta'(\rho_l)$ were calculated correctly from (37) by the PARI procedure sumalt with precision set to 2000 digits.

In the Fig.2 we present summary of these computer calculations. Since it is not possible to plot using standard plotting software as small values as $10^{-600}$ on the y-axis we present in the Fig. 2 the following quantity measuring the distance from $c^{g}_{100000}$ to the partial sums over zeros $\gamma_l$ in (27) and decreasing with number of zeros included in the sum:

$$y(n) = \left( \log \left( \frac{1}{k^{3/4}} \Re \left( \sum_{l=1}^{n} \frac{k^{\phi_l/2} \Gamma(\frac{3}{4} - \frac{1}{2} \phi_l)}{\zeta'\left(\frac{1}{2} + i\phi_l\right)} \right) - c^{g}_{k} \right) \right)^{-1}$$ (40)

where $k = 100000$ and the absolute value is necessary as the differences between successive approximants to $c^{g}_{100000}$ and $c^{s}_{100000}$ changes sign erratically. The consecutive terms in the series (27) behave like $e^{-\pi \phi_l/4}$ hence we expect that $y(n)$, by analogy with well known property of alternating series with decreasing terms, should behave like the first discarded term:

$$y(n) \sim \frac{4}{\pi \gamma_{n+1}}.$$ (41)

The Fig.2 confirms these considerations: initially $y(n)$ for all curves follows the prediction (41) and starting with $n$ for which the values of the $\zeta'(\rho_n)$ are incorrect adding further terms does not improve accuracy. Because of the exponential decrease of $\Gamma(\frac{3}{4} - \frac{1}{2} \phi_l)$ the contribution of further terms is suppressed and horizontal lines in Fig.2 are determined by the first $\gamma_l$ corresponding to the bad value of the derivative $\zeta'(\rho_n)$.

5 Final remarks

Although we have reached the agreement between $c^{g}_{100000}$ and $c^{s}_{100000}$ up to 996 places:

$$c^{g}_{100000} = 1.60975799 \ldots \leftarrow 980 \text{ digits} \rightarrow \ldots 291369630140 \times 10^{-9}$$

$$c^{e}_{100000} = 1.60975799 \ldots \leftarrow 980 \text{ digits} \rightarrow \ldots 291369629833 \times 10^{-9}$$

it means nothing about the validity of the RH. The refutation of the RH by computer methods seems to be as difficult as the analytical proof of its validity. As a possible precaution let us mention the paper “Strange Series and High Precision Fraud” written by Borwein brothers [6]. In this paper we found a few striking examples of the approximate equalities correct to many, many digits, which finally are not identities. The most fraudulent is the following

$$\sum_{n=1}^{\infty} \left| \frac{ne^{\sqrt{163}/9}}{2^n} \right| = 1280632$$ (42)
which is valid up to accuracy at least $10^{-500,000,000}$ but is not an identity.

At the end let us remark that the most accurate experiment in physics is the measurement of the ratio of the electric charge of the electron $e^-$ to the charge of the proton $e^+$ which is known to be something like $e^-/e^+ = -1 \pm 10^{-20}$, see [35]. Physicist believe that $e^- = -e^+$ exactly.

Acknowledgment: I would like to thank Dr. Keith Briggs and Prof. Krzysztof Maślanka for comments and remarks.
