The physics of granular matter has drawn a great deal of information from percolation theory ideas\textsuperscript{[1]}. Relatively simple models based on analogies have been implemented in order to describe realistic granular pile (static and dynamic) properties\textsuperscript{[2-6,7]}. Segregation\textsuperscript{[8]}, decompaction\textsuperscript{[9]} and avalanches\textsuperscript{[10]} point out to the existence of clusters. However, in describing such materials it is crucial to consider that they are not made of symmetrical entities. It is necessary to introduce at least one degree of freedom for the grain with some coupling to an external field. One can imagine that the degree of freedom, is called a "spin", coupled to a "magnetic field", though the "spin" can represent any non-magnetic physical feature of practical interest, like the grain roughness or shape feature. The spin role is to break the spatial isotropy symmetry. The direction of such a spin can represent the position of a grain with respect to neighboring entities, as well as a rotation process. The grain-grain interaction can be imagined to be some (elastic-like) potential containing information on the grain Young, rigidity, bulk modulus, and Poisson ratio, .. and geometric aspects\textsuperscript{[11]}. Generalizations to more complex spin models are immediately imagined.

Coniglio and Herrmann presented in\textsuperscript{[12]} a related view of the granular packing problem and adapted the Ising model and Sherrington-Kirkpatrick spin glass model to granular phenomena obtaining two phase transitions in the system. The short range exchange energy $J$ describing a "spin-spin interaction" is analogous in granular matter to the contact energy between grains. An interpretation of $J$ for flows can be found in Pandey et al.\textsuperscript{[13]} A constrained Ising spin chain has also been recently considered and studied as a toy model for granular compaction\textsuperscript{[14]}. Something which is fully appreciated is the difference in constructing piles in presence or not of vertical walls. A pyramidal pile has not necessarily the same structure, arches, ... as a pile in a silo. Moreover it is quite unrealistic to build a pile from a single grain faucet. Finally, due to its anisotropic shape a grain can rotate during its fall e.g. in responding to the local wind, or difference in pressure between the upper and lower grain surfaces. Such remarks have motivated us into re-examining a magnetic Tetris-like model (or a magnetic rain) for which the grain is characterized by a "spin" which can flip during its fall under some energetic condition.

In this paper the role of changing the depositing spin flipping probability during its fall in such a MBD (magnetic ballistic deposition) model is shown to influence the pile density, the pile "magnetization", and the cluster size distribution. In Sect\textsuperscript{[11]} we establish the algorithm rules and briefly comment upon them. In Sect\textsuperscript{[11]} we present numerical results for the density and the magnetization of the pile. (Sect\textsuperscript{[11]}). A critical percolation line is found separating two regimes for the size (mass) distribution of clusters. Finally, in Sect\textsuperscript{[11]} a brief conclusion can be found.

II. EXPERIMENTAL PROCEDURE

The algorithm for the so called $q$-MBD model, in contrast to the $\frac{1}{2}$-MBD model\textsuperscript{[15]}, goes as follows:

1. first, we choose a horizontal substrate of spins with a predetermined (for example antiferromagnetic-like or random) configuration; periodic boundary conditions are used;

2. a falling (up or down) spin is dropped along one of the lattice columns from a height $r_{\text{max}} + 5a$, where $r_{\text{max}}$ is the largest distance between an occupied cluster site and the substrate;

3. at each step down the spin can flip i.e., change its "sign"; the "up" direction has a probability $q$;

4. the spin goes down flipping until it reaches a site perimeter of the cluster at which time the local gain in the Ising energy

$$\beta E = -\beta J \sum_{<i,j>} \sigma_i \sigma_j$$

is calculated. The fall velocity is irrelevant and there is no backscattering. If the gain is negative
the spin sticks to the cluster immediately (sticking probability \(=1.0\)) and one goes back to step 2. In the opposite case the spin sticks to the cluster with a rate \(\exp(-\Delta \beta E)\) where \(\Delta \beta E\) is the local gain in the Ising energy. If the spin does not stick to the cluster it continues going down. Of course if the site just below the spin is occupied the spin immediately stops and sticks to the cluster.

5. After the spin stops one goes back to step 2.

In the \(1/2\)-MBD model [15] a finite field \(H\) and \(q = 0.5\) were assumed; in the present report we take \(H = 0\) but enlarge the permissible values of \(q\) to \([0, 1]\).

### III. NUMERICAL RESULTS

All results reported below are for a triangular lattice of horizontal size \(L = 100\), when the pile made of clusters has reached a 100 lattice unit height, and after averaging over 1000 simulations. The substrate consists of spins with random direction.

#### A. Density

We define the density of a cluster as \(\rho = \frac{\text{number of spins in the cluster}}{\text{number of sites on the lattice}}\) in which obviously the number of lattice sites in the denominator = 10 000.

Fig. 1 illustrates the behavior of the density with respect to the \(q\) and \(\beta J\) parameters. This figure convinces us that the results are symmetrical with respect to \(q = 0.5\). In the \(1/2\)-MBD model the density varies between 0.38 and 0.47 but in the present \(q\)-MBD a spread in density occurs, – from almost a completely compact pile in the AF case and large \(q\) to a loosely packed pile in the F case. The lowest density (0.38) occurs for \(\beta J = 0\) and for border values of \(q\), i.e. 0 and 1, in the F-case. For strong enough positive interactions (\(\beta J > 4\)) the density saturates toward the value \(\rho \approx 0.47\), in the F-case. In the AF case, the density varies between 0.38 and 1.0.

#### B. Magnetization

The dependence of the magnetization defined as

\[
M = \frac{n_+ - n_-}{n_+ + n_-}
\]

is shown in Fig. 2 as a function of \(\beta J\) and \(q\), where \(n_+\) and \(n_-\) are the number of up and down spins respectively, i.e. \(n_+ = 10000\rho_+\). \(M\) can be considered as a measure of the difference in grain orientations in the final packing.

The magnetization appears to be the same in the regions \((\beta J > 0, q < 0.5)\) and \((\beta J < 0, q > 0.5)\) (see Fig. 2). Notice that there is no terrace observed here in contrast to the \(1/2\)-MBD model case [15].

### IV. PERCOLATION

Define an up-spin percolating cluster as a cluster of up spins which extents from the bottom to the top of the sample. At fixed \(q\) and \(\beta J\) the fraction \(p\) of piles consisting in such a percolating cluster of up spins was computed. The behavior of \(p\) with respect to \(q\) for several values of the \(\beta J\) parameter is shown in Fig. 3. There is no percolating cluster for \(q < 0.75\) in the F-case and 0.85 in the AF-case. The \(q_0\) \((q_0(\beta J) := q\) when \(p > 0\)) dependence is shown in Fig. 4. Above \(q_0\) when \(p\) becomes finite a very fast growth of \(p\) is observed, at a given \(q_0\).

The differences between AF and F are understood if one recalls that the density in the AF case is much more sensitive to a change in \(q\) than in the F case, for which a change of \(q\) induces only a very small variation of the density – recall that the density in this case is \([0.38; 0.47]\).
FIG. 3: Dependence of the percolation probability $p_c$ on as a function of $q$ for different $\beta J$ values.

On the other hand a similar variation in $q$ values generates piles with a wide interval of densities in the AF case.

V. THE SIZE (MASS) DISTRIBUTION OF CLUSTERS

The number of clusters with $s$ size is called $N_s$. Its behavior is shown in Fig. 5 for low $q$ values. Notice that the $N_s$ dependence is approximately a straight line on a semi-log plot (all logs are neperian), i.e.

$$N_s(s) \propto e^{-k_E s} \quad \text{for} \quad q \approx 0,$$

where $k_E$ is a constant for a fixed $(\beta J, q)$ pair and $s$ is the cluster size (mass). Observe that the existence of a large cluster is more probable in the F case than in the AF case. This is expected when one recalls that the F case favours neighbors with a similar spin direction during the deposition.

For high $q$ values the $N_s$ dependence stops to be an exponential law and becomes a power law (see log-log plots on Fig. 6). Let us postulate

$$N_s(s) \propto s^{-k_P} \quad \text{for} \quad q \approx 1. \quad (4)$$

In order to find the values of $q$ for which the crossover effect occurs, i.e. from an exponential law regime (ELR) to a power law regime (PLR), we have estimated the slopes of the $N_s$ dependencies in both regimes. It seems that one should distinguish pile growth conditions with respect to $q(\beta J) < q_c$ and $q(\beta J) > q_c$.

Analogously to $N_s$ we can define $N_h$ as the number of hole clusters. Unlike the spin clusters there is no difference in $N_h$ dependencies between low and high values of $q$, – all $N_h$ dependencies seem to follow a power law.

VI. CONCLUSIONS

We have presented the extension of the MBD model \[15\] in order to find the role of the probability of spin flip during deposition (or the degree of freedom modification) in granular downward rain-like flow in 2D. The generalized model, hereby called $q$-MBD, is a nonequilibrium ballistic deposition model with one degree of freedom. One can imagine that the spins (grains) have different shapes and $q$ can be related to a wind strength such that the grains favour one or another position in order to minimize the pile energy. We have examined the cluster properties through two order parameters, since two characteristic fields ($J$ and $q$) are intrinsic to the model.

We have investigated the size, or ”mass”, of the spin clusters created through simulation of the nonequilibrium deposition. The ”quenching” of the degree of freedom on the cluster leads to two different regions of spin cluster geometric properties. In the low ”field” $q$ region the spin cluster mass distribution follows an exponential law, while in the high $q$ region the distribution is characterized by a power law. The transition between these two regimes is not sharp. The exponential law regime for high strength of interactions (i.e. $|\beta J| > 4$) seems to be universal, i.e. independent on the magnitude of the intrinsic parameters but depends only on the sign of $\beta J$, i.e. the characteristic contact interaction potential, – if they are ferromagnetic-like or antiferromagnetic-like, mechanically repulsive or attractive.
