Abstract. Gamma-ray binaries have been uncovered as a new class of Galactic objects in the very high energy sky (> 100 GeV). The three systems known today have hard X-ray spectra (photon index ∼1.5), extended radio emission and a high luminosity in gamma-rays. Recent monitoring campaigns of LSI +61°303 in X-rays have confirmed variability in these systems and revealed a spectral hardening with increasing flux. In a generic one-zone leptonic model, the cooling of relativistic electrons accounts for the main spectral and temporal features observed at high energy. Persistent hard X-ray emission is expected to extend well beyond 10 keV. We explain how Simbol-X will constrain the existing models in connection with Fermi Space Telescope measurements. Because of its unprecedented sensitivity in hard X-rays, Simbol-X will also play a role in the discovery of new gamma-ray binaries, giving new insights into the evolution of compact binaries.

Keywords: Radiation mechanisms: non-thermal – Stars: pulsars: general – Gamma rays: observations – X-rays: binaries

INTRODUCTION

Initially classified as standard high-mass X-ray binaries, gamma-ray binaries were soon set apart because of their low X-ray luminosity (L_X ∼ 10^{33}-10^{34} erg/s) and their resolved radio counter part. The new generation of Cherenkov telescopes has unveiled the real nature of these systems and established a new class of Galactic objects. Gamma-ray binaries emit most of their radiative output in the gamma-ray energy band from MeV up to about 10 TeV. They appear as point-like sources and exhibit an orbital modulated flux in the very high energy sky (VHE >100 GeV). Three systems are now solidly identified as gamma-ray binaries: PSR B1259−63 and LS 5039, both discovered by HESS in the Galactic Plane [1,2] and LSI +61°303 by MAGIC [3], later on confirmed by VERITAS [4]. Serendipitously detected by HESS [5], HESS J0632+057 is possibly the fourth system discovered so far [6] but more investigations are necessary to confirm its nature. PSR B1259−63 is comprised of a young rotation-powered 48 ms pulsar and a massive Be-star, but the nature of the compact object in the other systems remains unknown.

Particles in gamma-ray binaries are accelerated with high efficiency to several TeV energies, but the underlying physical mechanisms are still poorly understood. These systems are ideal objects for modeling the non-thermal radiation. The soft photon density is set by the massive star black body spectrum and the geometry of the system given by the orbital parameters. Observations in hard X-rays (20-100 keV) can constrain the existing

1 A recent soft gamma-ray repeater/anomalous X-ray pulsar like burst was observed by SWIFT (BAT) in the direction of LSI +61°303, possibly betraying the activity of a magnetar in this system [7].
models but suffer from low sensitivity of current telescopes. With its unprecedented sen-
sitivity *Simbol-X* will be able to better understand the physics at work in these systems,
giving stringent constraints on models. The study of these systems offers the opportu-
nity to explore a new class of Galactic object. We also explain here how *Simbol-X* will
identify new candidates and possibly serendipitously discover new systems.

**SIMBOL-X CAN CONSTRAIN EXISTING MODELS**

Independent of the nature of the compact object, the main spectral features exhibited
by gamma-ray binaries at high energy can be explained by a radiating population of
relativistic electrons. In a generic one zone leptonic model, particles are injected in a
region bathed in an ambient magnetic field and by soft photons from the massive star.
The non-thermal radiation is produced by synchrotron radiation and inverse Compton
scattering of the high energy electrons onto the soft stellar photons. Taking into account
the anisotropic effects due to the relative position of the compact object and the massive
star to the observer, spectra averaged along the orbit can be computed (Fig. 1).

**FIGURE 1.** Non-thermal radiation from LS 5039 expected in a one-zone leptonic model. Orbital
modulation is expected from X-rays up to VHE. Orbit (solid black line), superior conjunction (SUPC)
(blue dashed line) and inferior conjunction (INFC) (blue solid line) averaged spectra. See [8] for more
details.

In this model, a break energy is expected at the transition between the hard X-rays
and the high energy band (HE, GeV domain). This break is related to the synchrotron
radiation of the electrons and depends on the magnetic field strength as

$$\varepsilon_{\text{sync}} = 750 \left( \frac{T_\star}{4 \times 10^4 \, \text{K}} \right)^2 \left( \frac{R_\star}{10 \, \text{R}_\odot} \right)^2 \left( \frac{d}{0.1 \, \text{AU}} \right)^{-2} \left( \frac{B}{1 \, \text{G}} \right)^{-1} \text{keV},$$  \hspace{1cm} (1)

where $d$ is the orbital separation. Hence, *Simbol-X* observations in the hard X-ray band
in connection with the measurements of the *Fermi Space Telescope* at HE will constrain
the magnetic field.

Low variability correlated with the orbital period is expected. X-ray observations of
gamma-ray binaries have not revealed a clear orbital modulation until recently [9, 10] for
LS 5039 (see the contribution by M. Chernyakova in this volume for PSR B1259−63). Some binaries present more complicated patterns in their lightcurves. Long term RXTE monitoring of LSI +61°303 has revealed flaring episodes with no orbital phase correlations [11]. Spectral hardening with increasing flux have also been reported in the 2-10 keV band. Three flares of an hour long were clearly observed where the flux is one order of magnitude higher than the quiescence state. The doubling time is about 2 s, constraining the emitting size region to $\sim 6 \times 10^{10}$ cm, consistent with the expected size of the pulsar wind zone [12]. The sub-orbital variability might be due to the interaction with a clump from the massive star [13]. Simbol-X will certainly help to interpret this puzzling behaviour.

**SIMBOL-X CAN IDENTIFY NEW CANDIDATES**

**Candidates for follow-up**

A straightforward way to find new candidates in the hard X-ray sky is to look at the unidentified sources of the INTEGRAL (IBIS/ISGRI) survey catalog. About 25% of the sources detected are unidentified [14] and this fraction will probably remain unchanged by the end of the mission in 2012. The known gamma-ray binaries exhibit a rather hard (photon index $\sim 1.5$) steady spectrum with no high energy cut-off in hard X-rays observed so far. However, these criteria are not sufficiently discriminative to identify good candidates. Multi-catalog cross correlations are necessary to reduce the number of potential targets for Simbol-X. The first step is to look for a massive star coincident with the X-ray source and if possible find the orbital period of the system. Searching for an (extended) radio source increases the probability to find a candidate. Cross correlations with the Fermi and/or the Cherenkov telescopes observations in the Galactic Plane will definitively identify good candidates for follow-up by Simbol-X.

**Serendipitous detections**

Even if Simbol-X was not designed for a sky survey, the telescope will be pointed several times in the Galactic Plane. Here, we would like to give a rough estimate of potential serendipitous discoveries of new gamma-ray binaries with Simbol-X. The HESS survey of the Galactic Plane [15] has discovered two, perhaps three systems with a limiting flux of about $F_{\text{VHE}} > 10^{-12}$ erg cm$^{-2}$ s$^{-1}$ (2% Crab), over an area of about 300 deg$^2$. Assuming 500 pointings of 20 ks in the Galactic Plane, Simbol-X will cover about 20 deg$^2$ with a limiting flux $F_X(20-40 \text{ keV}) > 10^{-13}$ erg cm$^{-2}$ s$^{-1}$ (see e.g. [16]). Because $F_X \sim F_{\text{VHE}}$ in gamma-ray binaries, Simbol-X is able to observe 3 times deeper in the Galactic Plane than HESS. A system with a typical luminosity $L_X \sim 10^{33}$ erg/s would be detectable up to the Galactic Center. In spite of it small field of view ($\sim 12'$), Simbol-X would be able to discover serendipitously a couple of gamma-ray binaries. If many more systems are detected, then assuming a power-law distribution $N(L>L_0) \propto L_0^{-\alpha}$ for the luminosity function, this constrains $\alpha$ to exceed 1.
In this respect, CTA provides better prospects for serendipitous detections: with 10 times improvement in sensitivity (like Simbol-X) but with the ability to cover the whole Galactic Plane (like HESS), CTA should detect a dozen new gamma-ray binaries.

CONCLUSION

Observations of gamma-ray binaries in hard X-rays will benefit from the unprecedented sensitivity and performances of Simbol-X. Its higher angular resolution and sensitivity is of major importance for the detection and the identification of new systems in the Galaxy. Precise temporal and spectral measurements in hard X-rays in connection with higher energies will better constrain the existing models. Simbol-X will play an active role at a time when the Fermi Space Telescope and CTA will be operating, producing fruitful synergies. Undoubtedly, the discovery of new systems and the understanding of the physics at work in gamma-ray binaries will benefit from Simbol-X.
