(Dated: May 23, 2017)

We propose and analyze a high-fidelity hot gate for generic spin-resonator systems which allows for coherent spin-spin coupling, in the presence of a thermally populated resonator mode. Our scheme is non-perturbative in the spin-resonator coupling strength, applies to a broad class of physical systems, including for example spins coupled to circuit-QED and surface acoustic wave resonators as well as nanomechanical oscillators, and can be implemented readily with state-of-the-art experimental setups. We provide and numerically verify simple expressions for the fidelity of creating maximally entangled states under realistic conditions.

I. INTRODUCTION

Motivation.—The physical realization of a large-scale quantum information processing (QIP) architecture constitutes a fascinating problem at the interface between fundamental science and engineering [1, 2]. With single-qubit control steadily improving in various physical setups, further advances towards this goal currently hinge upon realizing long-range coupling between the logical qubits, since coherent interactions at a distance do not only relax some serious architectural challenges [3], but also allow for applications in quantum communication, distributed quantum computing and some of the highest tolerances in error-correcting codes based on long-distance entanglement links [2, 4, 5]. One particularly promising approach to address this problem is to interface qubits with a common quantum bus which effectively mediates long-range interactions between distant qubits, as has been demonstrated successfully for superconducting qubits [6, 7] and trapped ions [8].

Executive summary.—In the spirit of the celebrated Sørensen-Mølmer or similar gates for hot trapped ions [9–20], here we propose and analyze a generic bus-based quantum gate between distant (solid-state) qubits coupled to one resonator mode which allows for coherent spin-spin coupling, even if the mode is thermally populated. For certain times the qubits are shown to disentangle entirely from the (thermally populated) resonator mode, thereby providing a gate that is insensitive to the state of the resonator, without any need of cooling it to the ground state. While a similar gate has been considered for two superconducting qubits and (practically) zero temperature in Refs. [21, 22], here we show that this gate opens up the prospect of operating and coupling qubits at elevated temperatures ~ (1 − 4) K (as opposed to milli-Kelvin). This finding brings about the potential to integrate the qubit plane right next to the classical cryogenic electronics; therefore, our scheme may provide a solution to the solid-state QIP interconnect problem between the quantum (for encoding quantum information) and the classical layer (for classical control and read-out) [23]. Our approach should be accessible to a broad class of physical systems [24], including for example circuit QED setups with both (i) superconducting qubits [6, 21, 22, 25], and (ii) spin qubits [26–45], (iii) spins coupled to surface acoustic wave (SAW) resonators [46–48], and (iv) spins coupled to nanomechanical oscillators [49–53]; compare Fig. 1. We discuss in detail the dominant sources of errors for our protocol, due to rethermalization of the resonator mode and qubit dephasing, and numerically verify the expected error scaling.

II. THE SCHEME

We consider a set of spins (qubits) i = 1, 2, . . . with transition frequencies ωi coupled to a common (bosonic) cavity mode of frequency ωc, as described by the Hamiltonian (h=1)

\[ H = \omega_c a^\dagger a + \frac{\omega_i}{2} \sigma_i^z + \sum_j g_S \otimes (a + a^\dagger), \]  

with \( S = \sum_i \sigma^z_i \), \( \overline{S}^z = \sum_i \sigma^z_i \), where \( \sigma_i \) refer to the usual Pauli matrices describing the qubits, and \( a \) is the bosonic annihilation operator for the resonator mode. The operator \( S \) is a generalized (collective) spin operator which accounts for both transversal \( (\alpha=x, y) \) and longitudinal \( (\alpha=z) \) spin-resonator coupling; the unit-less parameters \( \eta_i \) capture potential anisotropies and inhomogeneities. The operator

![Figure 1: (color online). Schematic illustration for a generic spin-resonator system, comprising a set of spins \( \{\sigma_i\} \) (a) coupled to a common resonator mode (as provided by e.g. (a) a transmission line or (b) nanomechanical oscillators), with a non-vanishing thermal occupation.](image-url)
genicities in the single-photon (or single-phonon) coupling constants $g^a_n = \eta_n^c g$. Similar to existing (low-temperature) schemes [27, 43], the spin-resonator coupling $g=g(t)$ is assumed to be tunable on a timescale $\ll \omega_c^{-1}$; for details we refer to Appendix D.

Typically, for artificial atoms such as quantum dots the qubit transition frequencies $\omega_q$ are highly tunable. In what follows, we consider the regime where $\omega_q$ is much smaller than all other energy scales; therefore, for the purpose of our analytical derivation, effectively we take $\omega_q=0$. The robustness of our scheme against non-zero splittings ($\omega_q \neq 0$) will be discussed below. In this limit, the Hamiltonian given in Eq.(1) can be rewritten as

$$H = \omega_c \left( a + \frac{g}{\omega_c} S \right) \dagger \left( a + \frac{g}{\omega_c} S - \frac{g^2}{\omega_c} S^2 \right).$$

Using the relation $U a U^\dagger = a + (g/\omega_c) S$, with the unitary (polaron) transformation $U = \exp \left[ g/\omega_c S (a - a^\dagger) \right]$, Eq.(2) can be recast into the form

$$H = U \omega_c a^\dagger a - \frac{g^2}{\omega_c} S^2 \right) U^\dagger,$$

where we have used that $S$ commutes with $U$. The time-evolution governed by the Hamiltonian $H$ reads

$$e^{-iHt} = e^{-iuH_0 U^\dagger} U = U e^{-i\omega_c t_m a^\dagger \left( 1 + \frac{g^2}{\omega_c} S^2 \right) U^\dagger}$$

for certain times where $\omega_c t_m = 2\pi m$ (with $m$ integer), the first exponential equals the identity, $\exp \left[ -i\omega_c t_m a^\dagger a \right] = 1$, since the number operator $n = a^\dagger a$ has an integer spectrum $0,1,2,\ldots$. Thus, for $t_m = (2\pi/\omega_c) m$, the full time evolution reduces to

$$e^{-iHt} = e^{i\frac{\omega_c^2 t_m}{2} S^2}.$$  

This relation comes with two major implications: (i) Our approach is not based on a perturbative argument; therefore, apart from Eq.(5), the resonator-mediated qubit-qubit interaction does not lead to any further undesired, spurious terms. (ii) Since the unitary transformation given in Eq.(5) does not contain any operators acting on the resonator mode, it is completely insensitive to the state of the resonator [9, 10, 12], even though the spin-spin interactions present in $S^2$ have been established effectively via the resonator degrees of freedom; similar considerations have been applied for the case of two (superconducting) qubits for a zero temperature mode [22] and for small finite temperature $T$ in a classically modeled mode [21]. For specific times, the time-evolution in the polaron and the lab-frame fully coincide and become truly independent of the resonator mode, allowing for the realization of a thermally robust gate, without any need of cooling the resonator mode to the ground state.

Typically, for artificial atoms such as quantum dots the qubit transition frequencies $\omega_q$ are highly tunable. In what follows, we consider the regime where $\omega_q$ is much smaller than all other energy scales; therefore, for the purpose of our analytical derivation, effectively we take $\omega_q=0$. The robustness of our scheme against non-zero splittings ($\omega_q \neq 0$) will be discussed below. In this limit, the Hamiltonian given in Eq.(1) can be rewritten as

$$H = \omega_c \left( a + \frac{g}{\omega_c} S \right) \dagger \left( a + \frac{g}{\omega_c} S - \frac{g^2}{\omega_c} S^2 \right).$$

Using the relation $U a U^\dagger = a + (g/\omega_c) S$, with the unitary (polaron) transformation $U = \exp \left[ g/\omega_c S (a - a^\dagger) \right]$, Eq.(2) can be recast into the form

$$H = U \omega_c a^\dagger a - \frac{g^2}{\omega_c} S^2 \right) U^\dagger,$$

where we have used that $S$ commutes with $U$. The time-evolution governed by the Hamiltonian $H$ reads

$$e^{-iHt} = e^{-iuH_0 U^\dagger} U = U e^{-i\omega_c t_m a^\dagger a^\dagger \left( 1 + \frac{g^2}{\omega_c} S^2 \right) U^\dagger}$$

for certain times where $\omega_c t_m = 2\pi m$ (with $m$ integer), the first exponential equals the identity, $\exp \left[ -i\omega_c t_m a^\dagger a \right] = 1$, since the number operator $n = a^\dagger a$ has an integer spectrum $0,1,2,\ldots$. Thus, for $t_m = (2\pi/\omega_c) m$, the full time evolution reduces to

$$e^{-iHt} = e^{i\frac{\omega_c^2 t_m}{2} S^2}.$$  

This relation comes with two major implications: (i) Our approach is not based on a perturbative argument; therefore, apart from Eq.(5), the resonator-mediated qubit-qubit interaction does not lead to any further undesired, spurious terms. (ii) Since the unitary transformation given in Eq.(5) does not contain any operators acting on the resonator mode, it is completely insensitive to the state of the resonator [9, 10, 12], even though the spin-spin interactions present in $S^2$ have been established effectively via the resonator degrees of freedom; similar considerations have been applied for the case of two (superconducting) qubits for a zero temperature mode [22] and for small finite temperature $T$ in a classically modeled mode [21]. For specific times, the time-evolution in the polaron and the lab-frame fully coincide and become truly independent of the resonator mode, allowing for the realization of a thermally robust gate, without any need of cooling the resonator mode to the ground state.

This statement holds provided that rethermalization of the resonator mode can be neglected over the relevant gate time. The experimental implications for this condition will be discussed below.

To further illustrate Eq.(5), let us consider three paradigmatic examples: (1) For longitudinal coupling $g^a_n = 1$, $\eta_n^c = 0$, as could be realized (for example) with defect spins coupled to nanomechanical oscillators [50], we can identify the effective spin-spin Hamiltonian $H_{eff} = \Omega_m (\sigma^x + \sigma^z)^2$, which results in a relative phase $\phi = 4\Omega_m$ for the states $|\uparrow\uparrow\rangle$, $|\downarrow\downarrow\rangle$ as compared to the states $|\uparrow\downarrow\rangle$, $|\downarrow\uparrow\rangle$, respectively. By adding a local unitary on both qubits, such that $|1\rangle_i \rightarrow \exp (-i\phi/2) |1\rangle_i$ and $|0\rangle_i \rightarrow \exp (i\phi/2) |0\rangle_i$, in total for $\phi = \pi/2$ we obtain a controlled phase gate $U_{Cphase} = \text{diag} (1, 1, 1, -1)$, which gives a phase of $-1$ exclusively to $|11\rangle$, while leaving all other states invariant. Note that such a controlled phase gate can be implemented even in the presence of non-zero and inhomogeneous qubit level splittings ($\omega_q > 0$), when applying either fast local single qubit gates (to correct the effect of known $\omega_q \neq 0$) or standard spin-echo techniques (to compensate unknown detunings), thereby lifting the requirement of having a small qubit level splitting $\omega_q$; see Appendix H for details. (2) Again for longitudinal coupling $g^a_n = 1$, $\eta_n^c = 0$ and $N \geq 2$ qubits, Eq.(5) results in a unitary transformation $U = \exp \left[ -i\theta F^2 \right]$ gener-
ated by a non-linear top Hamiltonian describing precession around the $I_z = \sum \sigma_i^z$ axis with a rate depending on the $z$-component of angular momentum [12], which can be used to simulate non-linear spin models [12]. For transversal coupling with $S = \sigma_i^x + \sigma_i^y$, as could be realized (for example) with quantum dot based qubits embedded in circuit-QED cavities [29, 43] or SAW cavities [46, 47], we have $S^2 = 2 \times I + 2 \sigma_i^x \sigma_i^y$. Up to an irrelevant global phase $\phi_{gp}$ due to the first term $\sim I$, we get

$$e^{-iHt_m} = e^{-i\phi_{gp}} \exp \left[ i4\pi n \left( \frac{g}{\omega_c} \right)^2 \sigma_i^x \sigma_i^y \right],$$

(6)

which for $m \left( \frac{g}{\omega_c} \right)^2 = 1/16$ yields a maximally entangling gate, that is $U_{id}^g (1, 1/4 \left| \uparrow \downarrow \right\rangle = \frac{1}{\sqrt{2}} \left( \left| \uparrow \downarrow \right\rangle + i \left| \downarrow \uparrow \right\rangle \right)$ etc., i.e., initial qubit product states evolve to maximally entangled states, irrespectively of the temperature of the resonator mode, on a timescale $t_{max} = \pi/8g_{eff}$ (where $g_{eff} = g^2/\omega_c$); compare Fig.2 for an exemplary time evolution, starting initially from the product state $\rho(0) = \left| \uparrow \downarrow \right\rangle \left\langle \uparrow \downarrow \right| \otimes \rho_{th}(T)$, with the cavity mode in the thermal state $ho_{th}(T) = Z^{-1}\exp\left[-i\omega_c a^\dagger a\right]$, and $\beta = 1/k_BT$. Indeed entanglement peaks are observed at stroboscopic times $(\omega_c t_m = 2\pi m)$, independent of the temperature $T$, culminating in a maximally entangled state at time $t_{max}$.

III. COUPLING TO THE ENVIRONMENT

In the analysis above, we have ignored the presence of decoherence, which in any realistic setting will degrade the effects of coherent qubit-resonator interactions. Therefore, we complement our analytical findings with numerical simulations of the full master equation for the system’s density matrix $\rho$,

$$\dot{\rho} = -i[H, \rho] + \kappa (\bar{n}_{th} + 1) D[a] \rho + \kappa \bar{n}_{th} D[a^\dagger] \rho + \frac{\Gamma}{4} \sum_{i=1,2} D[\sigma_i^z] \rho,$$

(7)

where the generic spin-resonator Hamiltonian $H$ is given in Eq.(1) and the last two dissipative terms in the first line of Eq.(7), with $D[a] = \rho = a a^\dagger - \frac{1}{2} \{a^{\dagger} a, \rho\}$ and a cavity mode decay rate $\kappa = \omega_c/Q$, describe rethermalization of the cavity mode towards the thermal occupation $\bar{n}_{th} = \exp[\hbar \omega_c/k_BT] - 1^{-1}$ at temperature $T$; here, $Q$ is the quality-factor of the cavity. The last line in Eq.(7) describes dephasing of the qubits with a dephasing rate $\Gamma \sim 1/T_2^*$; where $T_2^*$ is the time-ensemble-averaged dephasing time. As discussed in detail in Appendix J, the noise model underlying Eq.(7) is accurate in the experimentally most relevant regime of weak spin-resonator coupling ($g \ll \omega_c$), where (within the approximation of independent rates of variation [54]) the interactions with the environment can be treated separately for spin and resonator degrees of freedom.

In Eq.(7) we have ignored single spin relaxation processes, since the associated timescale $T_1^*$ is typically much longer than $T_2^*$; still, relaxation processes could be included straightforwardly in our model by adding the decay terms $\rho = \cdots + T_1^{-1}\sum D[\sigma_i^x] \rho$ and the corresponding error (in-fidelity) could be analyzed along the lines of our analysis shown below (see Appendix N for details).

Numerical results.—To quantitatively capture the effects of decoherence, in the following we provide numerical results of the Master equation Eq.(7), for the initial product state $\rho(0) = \left( \left| \uparrow \downarrow \right\rangle \left\langle \uparrow \downarrow \right| \otimes \rho_{th}(T) \right)$, and (transversal) spin-resonator coupling with $\eta_1^\tau = 1$ and $\eta_2^\tau = \eta_1^\tau = 0$. As a figure of merit for our protocol, we quantify the state fidelity $F = \langle \Psi_{tar} | g \Psi_{tar} \rangle$ with the maximally entangled target state $| \Psi_{tar} \rangle = (| \uparrow \downarrow \rangle + i | \downarrow \uparrow \rangle) / \sqrt{2}$; here, $g = tr_a[\rho]$ refers to the density matrix of the qubits, with $tr_a[...]$ denoting the trace over the resonator degree of freedom. As shown in Appendix O, similar results can be obtained for the average gate fidelity. Typical results from our numerical simulations in the presence of noise are displayed in Fig.3. As expected from our analytical results, for $\omega_c t_m = 2\pi m$ the two qubits disentangle from the thermally populated resonator mode and systematically evolve towards the maximally entangled target state $| \Psi_{tar} \rangle$: for example, for $g/\omega_c = 1/8$ (as used in Fig.3), the spins evolve towards $U_{id}^g (1, 1/8 \left| \uparrow \downarrow \right\rangle = \cos (\pi/16) \left| \uparrow \downarrow \right\rangle + i \sin (\pi/16) \left| \downarrow \uparrow \right\rangle$ for $m=1$, $U_{id}^g (2, 1/8 \left| \uparrow \downarrow \right\rangle = \cos (3\pi/16) \left| \uparrow \downarrow \right\rangle + i \sin (3\pi/16) \left| \downarrow \uparrow \right\rangle$ for $m=2$, and $U_{id}^g (3, 1/8 \left| \uparrow \downarrow \right\rangle = \cos (3\pi/16) \left| \uparrow \downarrow \right\rangle + i \sin (3\pi/16) \left| \downarrow \uparrow \right\rangle$ for $m=3$.)
build-up culminates in the fully-entangling dynamics $i \sin (3\pi/16) |\uparrow\downarrow\rangle$ for $m=3$, before the entanglement build-up culminates in the fully-entangling dynamics $U_{id} (4,1/8) |\uparrow\downarrow\rangle = (|\uparrow\downarrow\rangle + i |\downarrow\uparrow\rangle)/\sqrt{2}$. For all practical purposes, this statement holds independently of the temperature $T$ and the associated thermal occupation of the resonator mode $\tilde{n}_c = k_B T/\hbar \omega_c$, provided that the quality factor of the cavity is sufficiently high; a quantitative statement specifying this regime will be given below. Moreover, while our analytical treatment has assumed $\omega_q=0$, we have numerically verified that the proposed protocol is robust against non-zero level splittings of the qubits $\omega_q/\omega_i \lesssim 0.1$; compare the dashed line in Fig. 3 and further information provided in Appendices G, H and K.

IV. GATE TIME REQUIREMENTS: ERROR SCALING

As described by Eq. (7), coupling to the environment leads to two dominant error sources: (i) rethermalization of the resonator mode with an effective rate $\sim \kappa_{th} \bar{n}_c$, and (ii) dephasing of the qubits on a timescale $\sim T_2^\ast$. For any hot gate, the associated gate time $t_{\text{gate}} \sim g_{\text{eff}}^{-1}$, with $g_{\text{eff}} = g^2/\omega_c = \mu^2 \omega_c$, has to be shorter than the timescale associated with the effective (thermally-enhanced) rethermalization rate $\kappa_{\text{eff}} = \kappa_{th} \bar{n}_c = k_B T/\hbar$. For the gate described above, this directly leads to the requirement

$$g^2/\omega_c \gg k_B T/Q \iff k_B T \ll Q \mu^2 \omega_c. \quad (8)$$

Thus, for $T=1K$ ($k_B T/2\pi \approx 20\text{GHz}$) and a cavity quality factor $Q \approx 10^5 - 10^6$, we need $g_{\text{eff}}/2\pi \gg (20-200)\text{kHz}$. Provided that our assumption $\omega_c > \omega_q$ is still fulfilled, for fixed temperature $T$, quality factor $Q$ and coupling $g$, relation (8) may be conveniently fulfilled by choosing $\omega_c$ sufficiently small, up to the lower limit $\omega_c \geq 4g$ (which is needed to fulfill $m \geq 1$; compare Appendix C) and at the cost of a potentially relatively large device (since the device dimensions scale with $\sim \lambda_c/\omega_c$). Conversely, for fixed $\mu = g/\omega_c$ [27, 47, 55], Eq. (8) can be achieved by choosing $\omega_c$ sufficiently large. In addition, the gate time has to be short compared to the qubit’s dephasing time $T_2^\ast \sim \Gamma^{-1}$, which gives the second requirement

$$g^2/\omega_c \gg \Gamma \iff \Gamma \ll \mu^2 \omega_c. \quad (9)$$

For concreteness, let us consider a specific setup where conditions (8) and (9) can be met with state-of-the-art technology: Quantum dots (QDs) have been successfully integrated with superconducting microwave cavities, with a relatively large charge-cavity coupling of $g_{\text{eff}}/2\pi \sim (20-100)\text{MHz}$ [35–38, 40]. For QD spin qubits a vacuum Rabi frequency of $g_{\text{eff}}/2\pi \sim 1\text{MHz}$ has been predicted [28, 29, 36], with the potential to increase this coupling to $\sim 10\text{MHz}$ with new, recently demonstrated cavity designs [56]. Furthermore, for superconducting transmission line resonators quality factors $Q \sim 10^6$ have been demonstrated [57]. Then, taking $g_{\text{eff}}/2\pi \sim 10\text{MHz}$, $\omega_c/2\pi \sim (0.16-1)\text{GHz}$, i.e., $g_{\text{eff}}/2\pi \approx (0.1-0.6)\text{MHz}$, and $Q=10^6$, conditions (8) and (9) can be met simultaneously for temperatures $T \sim 1K$ [since $T \ll 5(30)K$ to fulfill condition (8) for $g_{\text{eff}}/2\pi \approx 0.1(0.6)\text{MHz}$ and dephasing timescales $T_2^\ast \sim 100\mu s$ [since $T/2\pi \ll (0.1-0.6)\text{MHz}$ to fulfill condition (9)], as has been demonstrated with isotopically purified Si samples [58]. Therefore, a faithful implementation of our gate will not require cooling to milli-Kelvin temperatures. Similar promising estimates also apply to spin-qubits coupled to SAW-resonators; compare Appendix I.

In the following, we quantify the infidelities induced by the two error sources outlined above: Rethermalization of the resonator mode during the gate leads to errors (infidelities) if the resonator is entangled with the qubits. Due to leakage of which-way information, resonator noise leads to qubit dephasing at a rate propor-
tional to the relevant separation in phase space, that is the square of the resonator displacement $\mu = g/\omega_c$ [50]. The effective rethermalization-induced dephasing rate for the qubits is then $\Gamma_{\text{eff}} = \kappa n_{\text{th}} (g/\omega_c)^2$. To obtain a simple estimate for the rethermalization-induced error, this effective rate $\Gamma_{\text{eff}}$ is multiplied with the relevant gate time which scales as $t_{\text{gate}} \sim \omega_c g^2$, yielding the error $\xi \sim (\kappa/\omega_c) n_{\text{th}}$, which is independent of the spin-resonator coupling strength $g$ [22, 50]; for a full analytical derivation we refer to Appendix L. However, since the overall gate time $t_{\text{gate}} \sim \omega_c g^2$ increases for small $\mu = g/\omega_c$, errors will accumulate due to direct qubit decoherence processes. Accordingly, errors due to qubit dephasing are expected to scale as $\xi \sim \Gamma/\mu_{\text{eff}} \sim \mu^{-2} \Gamma/\omega_c$. This simple linear scaling holds for a Markovian noise model where qubit dephasing is described by a standard pure dephasing term [compare Eq.(7)] leading to an exponential loss of coherence $\sim \exp[-t/T_2^*]$; for non-Markovian qubit dephasing a better, sub-linear scaling can be expected [46, 50]. For small infidelities ($\mu_{\text{eff}} / \kappa_{\text{eff}} \Gamma$, $\Gamma$), the individual linear error terms due to cavity rethermalization and qubit dephasing can be added independently, yielding the total error
\[
\xi \approx \alpha_n (\kappa/\omega_c) n_{\text{th}} + \alpha_\Gamma \Gamma/\omega_c. \quad (10)
\]
This simple linear error model has been verified numerically; compare Fig.4. Based on these results we extract the coefficients $\alpha_n \approx 4$ (which is approximately independent of $g$ [22]; compare Appendices K and L for details) and $\alpha_\Gamma \approx 0.1/\mu^2$. For $g_{\text{dp}}/2\pi \approx 10 \text{MHz}$ [28, 29, 56], a relatively low resonator frequency $\omega_c/2\pi = 16 \text{GHz}$, $T=1 \text{K}$ (corresponding to $n_{\text{th}} \approx 130$), $Q = 10^5$ [56, 57] and a realistic dephasing rate $\Gamma/2\pi \approx 0.1 \text{MHz}$ [58], that is $\kappa/\omega_c n_{\text{th}} = 1.3 \times 10^{-3}$ and $\Gamma/\omega_c \approx 6 \times 10^{-4}$, our estimates then predict an overall infidelity of $\xi \approx 2\%$, with the potential to reach error rates $\xi \approx 0.2\%$ below the threshold for quantum error correction for state-of-the-art experimental parameters ($Q \approx 10^6$, $\Gamma/2\pi \approx 10 \text{kHz}$) [4, 57, 58]. This simple estimate compares well with other bus-based, two-qubit (hot) gates reaching fidelities $\sim 97\%$ [20, 50, 59] and has been corroborated by numerical simulations that fully account for higher-order errors; compare the density plot in Fig.4(c). We like to emphasize that, due to the fundamental temperature-insensitivity of our gate, technological improvements in the achievable $Q$-factor directly translate to a proportional reduction of thermalization-induced errors and therefore increase the acceptable temperature. Note that the error estimate given in Eq.(10) assumes perfect timing of the gate, as the maximum fidelity is reached exactly at time $t_{\text{max}}$, whereas under experimentally realistic conditions there will be a residual error due to imperfect timing of the gate. However, as shown in Appendix K, for sufficiently small, but realistic timing accuracies of $\omega_c/2\pi \Delta t \lesssim 1\%$ and small spin-resonator coupling $g/\omega_c \lesssim 1/16$ (implying small oscillation amplitudes), the effects of time-jitter become negligible.

V. CONCLUSIONS & OUTLOOK

To conclude, we have proposed and analyzed a high-fidelity hot gate for generic spin-resonator systems which allows for coherent spin-spin coupling, even in the presence of a thermally populated resonator mode. While we have mostly focused on just two spins, our scheme fully applies to more than two spins, which should allow for the preparation of maximally entangled multi-partite states; as shown in Ref.[11] in the context of trapped ions, a propagator of the form given in Eq.(5) applied to the initial product state $|00\cdots0\rangle$ may be used to generate states of the form $1/\sqrt{2} (|00\cdots0\rangle + e^{i\phi} |11\cdots1\rangle)$, where $|00\cdots0\rangle$ and $|11\cdots1\rangle$ are product states with all qubits in the same state $|0\rangle$ or $|1\rangle$, respectively.

Appendices

The following Appendices provide additional background material to specific topics of the main text. They are structured as follows: In Sec.A we provide typical thermal occupation numbers $n_{\text{th}}$ for relevant experimental parameter regimes. In Sec.B we compare the ideal evolution in the lab frame to the one in the polaron frame. In Sec.C we derive the ideal gate time $t_{\text{max}}$. In Sec.D we discuss a prototypical implementation of a spin-resonator system that allows for time-dependent control of the spin-resonator $g = g(t)$, as required for the faithful realization of the proposed hot gate. In Sec.E we discuss the standard approach to coupling spins via a common resonator mode in the disperersive regime, in which, in contrast to the proposed hot gate, the spin degrees of freedom do not fully disentangle from the resonator mode. In Sec.F we compare our general result to a perturbative calculation in the framework of a Schrieffer-Wolff transformation. In Secs.G and H we analyze in detail the effects coming from a non-zero qubit level splitting ($\omega_q/\omega_c > 0$). In Sec.I we provide further details on how to implement experimental candidate systems governed by the class of Hamiltonians given in Eq.(1), using quantum dots embedded in high-quality surface acoustic wave (SAW) resonators. In Sec.J we provide a microscopic derivation of the Master equation given in Eq.(7) of our manuscript. In Sec.K we present further results based on the numerical simulation of the master equation given in Eq.(7) of the
main text. In Sec.L we derive an analytical expression for rethermalization-induced errors, while Sec.M provides an analytical model for dephasing-induced errors. In Sec.N we address in detail errors induced by relaxation processes. In Sec.O we conclude with a discussion on the average gate fidelity.

Appendix A: Thermal Occupation

Here, we first provide typical thermal occupation numbers $\bar{n}_{\text{th}}$ for relevant experimental parameter regimes. At a temperature $T = 4\, \text{K}$, a (mechanical) oscillator of frequency $\omega_c/2\pi \sim (1 - 10)\, \text{GHz}$ has a thermal equilibrium occupation number much larger than one, $\bar{n}_{\text{th}} \approx 8 - 80$: compare Fig.5.

Appendix B: Polaron vs. Lab Frame

In this Appendix we show that for stroboscopic times the ideal time evolution in the lab frame fully coincides with the one in the polaron frame.

In the ideal (noise-free) scenario, the evolution of the system in the lab frame, comprising both spin and resonator degrees of freedom, is described by Schrödinger’s equation

$$i\frac{d}{dt} |\psi\rangle_t = H |\psi\rangle_t.$$  (B1)

In the polaron frame, the time evolution is governed by

$$i\frac{d}{dt} |\tilde{\psi}\rangle_t = \tilde{H}_0 |\tilde{\psi}\rangle_t,$$  (B2)

where $|\tilde{\psi}\rangle_t = U^\dagger |\psi\rangle_t$, $U = \exp \left[ i S \left( a - a^\dagger \right) \right]$, and $\tilde{H}_0 = U^\dagger H U = \omega_c a^\dagger a - \frac{\mu^2}{\omega_c} S^2$; the polaron transformation $U$ entangles spin with resonator degrees of freedom. The solution to Eq.(B2) reads $|\tilde{\psi}\rangle_t = \exp \left[ -i \omega_c t a^\dagger a \right] |\psi\rangle_0$. Using the relation $\exp \left[ -i \omega_c t a^\dagger a \right] = \exp \left[ -i 2\pi m a^\dagger a \right] = 1$ for stroboscopic times ($\omega_c t_m = 2\pi m$, with $m$ integer), full time evolution in the polaron frame reduces to

$$|\tilde{\psi}\rangle_{t_m} = e^{i 2\pi m \mu^2 S^2} |\psi\rangle_0.$$  (B3)

Transforming back to the lab frame with $|\psi\rangle_t = U |\psi\rangle_{t_m}$ and using that $U$ commutes with the propagator $\exp \left[ i 2\pi m \mu^2 S^2 \right]$, we obtain the (stroboscopic) solution in the lab frame, $|\psi\rangle_{t_m} = e^{i 2\pi m \mu^2 S^2} |\psi\rangle_0$, which fully coincides with the one in the polaron frame.

Appendix C: Gate Time

Ideally, the gate time $t_{\text{gate}}$ has to fulfill two conditions: (i) it has to be chosen stroboscopically, that is $\omega_c t_{\text{gate}} = 2\pi m$, with $m = 1, 2, \ldots$; (ii) the parameters such that $\mu^2 = 1/16$ in order to obtain a maximally-entangling gate (in the absence of noise). Combination of (i) and (ii) then yields the ideal gate time

$$t_{\text{max}} = \frac{\pi}{8 g_{\text{eff}}},$$  (C1)

as given in the main text. The gate time $t_{\text{max}}$ should be short compared to the relevant noise timescales, which yields the requirement $g_{\text{eff}} \gg \kappa_{\text{eff}} / \Gamma$. In principle, large values of $g_{\text{eff}} = g^2 / \omega_c$ can be obtained by choosing the resonator frequency $\omega_c$ sufficiently small, provided that $\omega_c$ can be tuned independently of $g$. This can be done up to the lower bound $\omega_c \geq 4 g$ which follows directly from the requirement $m = 1/ (16 \mu^2) \geq 1$.

Appendix D: Time-dependent Control of the Spin-Resonator Coupling

In this Appendix we discuss in detail a prototypical implementation of a spin-resonator system that allows for time-dependent control of the spin-resonator coupling $g = g(t)$, as required for the faithful realization of the proposed hot gate. Here, we first focus on a charge qubit embedded in a lithographically defined double quantum dot (DQD) containing a single electron, and then extend our analysis to a singlet-triplet spin qubit made out two electrons in such a DQD. Based on the electric dipole interaction, this type of device may be coupled either to a microwave transmission line resonator in a circuit-QED-like setup, as investigated theoretically and experimentally in (for example) Refs.[35, 36, 40], or a surface-acoustic-wave resonator, as described in Refs.[46, 47].

Our approach then employs standard all-electrical manipulation strategies, in which external, tunable gate voltages are used for (basically) in-situ control of the effective spin-resonator coupling [20], provided that standard adiabaticity conditions are fulfilled [43], with the
additional requirement of having a relatively small qubit transition frequency $\omega_q$ when the (hot) gate is turned on; as shown in Sec.H, this condition can be dropped, however, for longitudinal spin-resonator coupling.

1. Double Quantum Dot Charge Qubit

The Hamiltonian describing a tunnel-coupled DQD in the single-electron regime coupled to a cavity of frequency $\omega_c$ is given by [31–33]

$$H = \frac{\epsilon}{2} \tau^z + t_c \tau^x + \omega_c a^\dagger a + g_{ch} \tau^z \otimes (a + a^\dagger), \quad (D1)$$

where $\epsilon$ is the (tunable) level detuning between the dots, $t_c$ gives the (tunable) tunnel coupling, and $g_{ch}$ refers to the single photon (phonon) coupling strength between the resonator and the DQD. The electron charge state is described in terms of orbital Pauli operators defined as $\tau^z = |L\rangle \langle L| - |R\rangle \langle R|$ and $\tau^x = |L\rangle \langle R| + |R\rangle \langle L|$, respectively, with $|L\rangle (|R\rangle)$ corresponding to the state where the electron is localized in the left (right) dot, while $a^\dagger (a)$ are the standard resonator creation (annihilation) operators.

Diagonalization of the first two terms in the Hamiltonian $H$, that is $H_{ch} = \epsilon \tau^z + t_c \tau^x$, yields the electronic charge eigenstates

$$|+\rangle = \cos \theta |L\rangle + \sin \theta |R\rangle, \quad (D2)$$

$$|-\rangle = - \sin \theta |L\rangle + \cos \theta |R\rangle, \quad (D3)$$

where the mixing angle is given by $\tan \theta = 2t_c / (\epsilon + \omega_q)$, and $\omega_q = \sqrt{\epsilon^2 + 4t_c^2}$ refers to the energy splitting between the eigenstates $|\pm\rangle$; compare Fig.6. The logical qubit basis is (by definition) given by the superposition states $|\pm\rangle = (|L\rangle \pm |R\rangle) / \sqrt{2}$ at the charge degeneracy point ($\epsilon = 0$), where to first order the qubit is insensitive to charge fluctuations ($d\omega_q / d\epsilon = 0$). In the eigenbasis of $H_{ch}$, and after a simple gauge transformation ($a \rightarrow -a, a^\dagger \rightarrow -a^\dagger$), the spin-resonator Hamiltonian given in Eq.(D1) can be rewritten as

$$H = \frac{\omega_q}{2} \sigma_z^2 + \omega_c a^\dagger a + (g^x \sigma_x - g^z \sigma_z) \otimes (a + a^\dagger). \quad (D4)$$

Here, we have introduced the Pauli operators as $\sigma^z = |+\rangle \langle +| - |-\rangle \langle -|$, and $\sigma^x = |+\rangle \langle -| + |-\rangle \langle +|)$; the transversal and longitudinal coupling parameters are given by

$$g^x = g_{ch} \frac{2t_c}{\omega_q}, \quad (D5)$$

$$g^z = g_{ch} \frac{\epsilon}{\omega_q}. \quad (D6)$$

By redefining the interdot detuning parameter as $\epsilon \rightarrow -\epsilon$ (or, equivalently by relabeling $|L\rangle \leftrightarrow |R\rangle$), the spin-resonator Hamiltonian $H$ may be expressed as [26, 31]

$$H = \frac{\omega_q}{2} \sigma_z^2 + \omega_c a^\dagger a + (g^x \sigma_x + g^z \sigma_z) \otimes (a + a^\dagger). \quad (D7)$$

Both, the effective transversal coupling parameter $g^x$ as well as the longitudinal coupling parameter $g^z$ can be controlled via rapid all-electrical tuning of either the interdot detuning parameter $\epsilon$ and/or the tunnel splitting $t_c$ (recall $\omega_q = \sqrt{\epsilon^2 + 4t_c^2}$ [26, 30, 32, 33, 35, 43]). As shown in Fig.7, the transversal coupling parameter $g^x$ is maximized around $\epsilon = 0$ (that is, when the electron is de-localized in both dots), while it is strongly suppressed for $|\epsilon| \gg t_c$. Conversely, the longitudinal coupling parameter $g^z$ is maximized for $|\epsilon| \gg t_c$, while it is strongly suppressed for small detuning $|\epsilon| \ll t_c$. Note that, outside of our regime of interest, in the limit where $\delta, g_{ch} \ll \omega_c$ (with $\delta = \omega_q - \omega_c$) one can perform a rotating-wave approximation yielding the standard Jaynes-Cummings Hamiltonian, as widely discussed in the literature (see e.g. Refs.[26, 30, 32, 33, 35, 46]).
Then, since the parameters $\epsilon (t)$ and $t_c (t)$ can be tuned all-electronically on very fast timescales, the protocol for the proposed hot gate proceeds as follows: (i) For $\epsilon \sim 0$, the hot gate is turned on, with $g^z \approx g_{ch}$ and $g^z \sim 0$ (corresponding to purely transversal spin-resonator coupling as discussed extensively in the main text). In this regime, the qubit level splitting is set by the (highly tunable) tunnel-coupling, according to $\omega_q \approx 2 t_c$, which should be chosen to be much smaller than the cavity frequency ($t_c \ll \omega_c$) in order to satisfy the requirements of the proposed hot gate. (ii) After some well-controlled (stroboscopic) time $t_m = 2 \pi m / \omega_c$, the hot gate can be turned off by sweeping $\epsilon$ to large detuning values $\epsilon \gg t_c$.

Both regimes are readily achievable in the quantum dot setting: Due to the exponential dependence of tunnel coupling strength $t_c$ on gate voltage, the interdot barrier characterized by $t_c$ can be varied from about 100$\mu$eV (verified by the broadening of the time-averaged charge transition; note that for much larger tunnel couplings, two neighboring dots become one single dot) all the way down to less than $10^{-12}$eV to $10^{-6}$GHz (corresponding to a millisecond timescale, as verified by real-time detection of single charges hopping on or off the dot) [60], which is five to six orders of magnitude smaller than realistic cavity frequencies. Similarly, the detuning $\epsilon$ between the dots can be varied anywhere between zero and a positive or negative detuning equal to the addition energy, at which point additional electrons are pulled into the dot. The typical energy scale for the addition energy is very large ($\sim 1 - 3$meV) [60].

Note that in the proposed off-setting [step (ii)] the qubits and the cavity are not strictly decoupled due to the non-vanishing longitudinal term (compare Fig.7). For $g_{ch} \ll \omega_c$, this coupling is usually neglected within a rotating-wave approximation [26, 32, 35]. However, here we provide an exact treatment, that takes into account the energy shifts and couplings arising from the (fast rotating) qubit-cavity coupling term. For $g^z = 0$, the Hamiltonian $H$ can be diagonalized exactly, yielding the eigenstates $\ket{\sigma} \otimes D(\sigma \alpha) \ket{n}$ with the corresponding eigenenergies $\epsilon (\sigma, n) = \sigma \epsilon_0 / 2 - g^z / \omega_c + n \omega_c$, with $\sigma = \pm$ for spin-up and spin-down, respectively, the displacement operator $D (\alpha) = \exp [\alpha a^\dagger - \alpha^* a]$ and $| n \rangle$ denoting the usual Fock states. This treatment can be extended straightforwardly to more than one qubit.

While the analysis above has focused on a single charge qubit, in the following we consider two qubits of this type, coupled to a common resonator mode. Then, for two qubits and purely longitudinal spin-resonator coupling, in the presence of a non-zero (and potentially large, $\omega_q \sim |\epsilon|$) level splitting $\omega_q$, the time evolution generated by the Hamiltonian $H$ reads

$$ U (t_m) = e^{-i H t_m} = e^{-i \frac{2 \pi m}{\omega_c} U_{id} (t_m)} U_{id}^z (t_m), \quad (D8) $$

with the ideal evolution $U_{id} (t_m) = \exp \left[ i 4 \pi m \mu B / 2 \sigma^z \right]$, up to an irrelevant global phase. Therefore, in the regime $|\epsilon| \gg t_c$, a general two-qubit state $|\Psi_{2q}\rangle = c_{00} |\uparrow\uparrow\rangle + c_{01} |\uparrow\downarrow\rangle + c_{10} |\downarrow\uparrow\rangle + c_{11} |\downarrow\downarrow\rangle$ evolves as

$$ U (t_m) |\Psi_{2q}\rangle = e^{i 2 \pi m \frac{\omega_q}{\omega_c}} c_{00} |\uparrow\uparrow\rangle + e^{-i 2 \pi m \frac{\omega_q}{\omega_c}} c_{11} |\uparrow\uparrow\rangle + e^{-i \frac{8 \pi m \mu B}{\omega_c}} (c_{01} |\uparrow\downarrow\rangle + c_{10} |\downarrow\uparrow\rangle) \quad (D9) $$

When tuning the qubit level splitting on resonance ($\omega_q \approx |\epsilon| = \omega_c$), such that $\exp [\pm i 2 \pi m \omega_q / \omega_c] = 1$ for all $m = 1, 2, 3, \ldots$; for certain times $t^* = 2 \pi m / \omega_c = \pi / 2 g_{ch}$, this unitary returns the original state, since $U_{id}^z (t^*) = 1$, and therefore, absent any other noise sources, leaves the (typically entangled) state prepared by the first step (i) with $g^z = g_{ch}$, $g^z = 0$ unaffected; recall that $\mu = g_{ch} / \omega_c = 1 / 4, 1 / 8, \ldots$ is chosen commensurately. While this statement holds for any two qubit state $|\Psi_{2q}\rangle$, this effect becomes even simpler to see when the qubits are initialized in any of the four computational basis states $\{ |\sigma, \sigma'\rangle \}$. Here, the ideal transversal gate (i) first prepares maximally entangled states, according to

$$
\begin{align*}
|\downarrow, \downarrow\rangle &\rightarrow \frac{1}{\sqrt{2}} (|\uparrow, \downarrow\rangle + i |\downarrow, \uparrow\rangle), \\
|\uparrow, \downarrow\rangle &\rightarrow \frac{1}{\sqrt{2}} (|\uparrow, \uparrow\rangle + i |\downarrow, \downarrow\rangle), \\
|\downarrow, \uparrow\rangle &\rightarrow \frac{1}{\sqrt{2}} (|\downarrow, \downarrow\rangle + i |\uparrow, \uparrow\rangle), \\
|\uparrow, \uparrow\rangle &\rightarrow \frac{1}{\sqrt{2}} (|\uparrow, \downarrow\rangle + i |\downarrow, \uparrow\rangle),
\end{align*}
$$

which subsequently in stage (ii) where $(g^x = 0, g^z = g_{ch})$ are left invariant $\forall m = 1, 2, \ldots$; Eqs.(D12) and (D13) even hold independently of $\omega_q$.

The charge-qubit-based scheme discussed above can be extended to (switchable) coupling between the resonator mode and the electron’s spin, by making use of various mechanisms which hybridize spin and charge degrees of freedom, as provided by spin-orbit interaction or inhomogeneous magnetic fields [29, 30, 41, 43]. Such an implementation that easily generalizes to $N$ qubits and would allow to fully turn off any coupling to the cavity mode (and to do so selectively for any chosen subset of qubits) is discussed in the next section.

2. Double Quantum Dot Spin Qubit

Let us now extend our treatment to singlet-triplet spin qubits in quantum dots, where logical qubits are encoded in a two-dimensional subspace of a higher-dimensional two-electron spin system, as investigated theoretically and experimentally (for example) in Refs.[60, 61]. This approach successfully combines spin and charge manipulation, making use of the very long coherence times associated with spin states and, at the same time, enabling efficient readout and coherent manipulation of coupled spin states based on intrinsic interactions [27].

In contrast to the charge qubit setting discussed above (where the electron’s charge will always couple to the resonator mode with the type of coupling depending on the
particular parameter regime), in this setting the coupling to the cavity mode can be turned off completely, since the dipole-moment associated with the singlet-triplet qubit (which in this case determines the spin-resonator coupling) vanishes in the so-called \((1,1)\) regime: here, \((m,n)\) refers to a configuration with \(m(n)\) electrons in the left (right) dot, respectively.

We focus on the typical regime of interest, where (following the standard notation) the relevant electronic levels are given by the triplet states \(|T_+\rangle = |\uparrow\downarrow\rangle\), \(|T_-\rangle = |\downarrow\uparrow\rangle\), and \(|T_0\rangle = (|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)/\sqrt{2}\), as well as the singlet states \(|S_{11}\rangle = (|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)/\sqrt{2}\) and \(|S_{02}\rangle = d_{L\uparrow}^\dagger d_{R\downarrow}^\dagger |0\rangle\) with \(|\sigma\sigma\rangle = d_{L\sigma}^\dagger d_{R\sigma}^\dagger |0\rangle\); the fermionic creation (annihilation) operators \(d_{i\sigma}^\dagger (d_{i\sigma})\) create (annihilate) an electron with spin \(\sigma = \uparrow, \downarrow\) in the orbital \(i = L, R\). For sufficiently large magnetic field \(B\), the levels \(|T_+\rangle\) and \(|T_-\rangle\) are far detuned and can be neglected for the remainder of the discussion. Therefore, in the following, we restrict ourselves to the subspace \(\{|T_0\rangle, |S_{11}\rangle, |S_{02}\rangle\}\), as schematically depicted in the inset of Fig.8. In the relevant regime of interest, the electronic DQD system is described by the Hamiltonian [27]

\[
H_{\text{DQD}} = \frac{t_c}{2} (|S_{02}\rangle \langle S_{11}| + \text{h.c.}) + \Delta (|T_0\rangle \langle S_{11}| + \text{h.c.}) - \epsilon |S_{02}\rangle \langle S_{02}|, \tag{D14}
\]

where (as before) \(t_c\) refers to the interdot tunneling amplitude, \(\epsilon\) is the interdot detuning parameter, and \(\Delta\) is a static magnetic field gradient between the two dots which couples singlet and triplet states. State preparation, measurement, single-qubit gates and local two-qubit gates can be achieved by tuning the bias \(\epsilon [60]\). Tunnel coupling between the singlet states \(|S_{11}\rangle\) with \((1,1)\) charge occupation and \(|S_{02}\rangle\) with \((0,2)\) charge occupation yields the hybridized singlet states \(|S_{\pm}\rangle\). The arrows indicate schematically how to turn on and off the effective spin resonator coupling, by changing the effective dipole moment associated with the qubit. Inset (b): Relevant level diagram in the subspace \(\{|T_0\rangle, |S_{11}\rangle, |S_{02}\rangle\}\).
Projection onto the electronic low-energy subspace \( \{|T_0\}, |S_-\rangle \) (i.e., projecting out the high-energy level \( |S_+\rangle \)) then leads to (to lowest order in \( \sim g_0/\epsilon_+ \)) to the effective spin resonator system

\[
H = J (|S_-\rangle \langle S_-| - \Delta \sin \theta (|T_0\rangle \langle S_-| + \text{h.c.}) + \omega_c a^\dagger a \\
+ g_0 \cos^2 \theta |S_-\rangle \langle S_-| (a + a^\dagger) ,
\]

which includes a tunable spin resonator coupling, explicitly given by

\[
g_{sp}/g_0 = \cos^2 \theta = \frac{1}{2} \left( 1 + \frac{\epsilon}{\sqrt{\epsilon^2 + t_c^2}} \right).
\]

As demonstrated in Fig.9, the effective coupling \( g_{sp} \) may be turned on and off by sweeping the detuning parameter \( \epsilon \) (closely following the functional dependence of \( \omega_0/\epsilon_+ \)), i.e. by controlling the admixture of \( |S_{02}\rangle \) to the hybridized singlet level \( |S_-\rangle \). For large, negative values of \( \epsilon \) this admixture vanishes \( (\cos^2 \theta \to 0) \), such that the effective dipole moment associated with the qubit vanishes and therefore the spin resonator coupling is switched off. The type of spin-resonator coupling (transversal versus longitudinal) may be controlled by the magnetic gradient \( \Delta \), as can be done using e.g. a nanomagnet or nuclear Overhauser fields [43, 60]. While for longitudinal spin-resonator coupling the resonator frequency \( \omega_c \) may be comparable or even smaller than the effective qubit level splitting \( J \) (see Sec. H for details), in the case of transversal coupling the effective qubit level splitting needs to be much smaller than the cavity frequency, that is \( |J(t_c, \epsilon)| \approx |t_c^2/4\epsilon| \ll \omega_c \), but, at the same time, \( \epsilon_+ \approx |\epsilon| + t_c^2/4|\epsilon| \gg \omega_c \) should be fulfilled in order to neglect the high-energy level \( |S_+\rangle \). Still, both requirements can be satisfied by choosing the parameters as \( t_c, \omega_c \ll |\epsilon| \).

Appendix E: Spin-Spin Coupling in Dispersive Regime

We consider two identical spins homogeneously coupled to a common resonator mode. The dynamics are assumed to be governed by the Jaynes-Cummings Hamiltonian

\[
H = \Delta (S_1^+ + S_2^+) + g \left[ a \left( S_1^+ + S_2^+ \right) + a^\dagger \left( S_1^- + S_2^- \right) \right],
\]

which is valid within the rotating-wave approximation for \( \sqrt{n_{th}} g/\Delta \ll \omega_c \), with the detuning \( \Delta = \omega_q - \omega_c \). In the following we consider the dispersive regime, where the spin-resonator coupling is strongly detuned \( (\sqrt{n_{th}} g \ll \Delta) \). In this regime, the spin-resonator coupling can be treated perturbatively. To stress the perturbative treatment we write

\[
H = H_0 + H_1,
\]

\[
H_0 = \Delta S^z,
\]

\[
H_1 = g \left( a S^+ + a^\dagger S^- \right),
\]

where \( S^\alpha = S_1^\alpha + S_2^\alpha \) (for \( \alpha = \pm, z \)) are collective spin operators. We perform a standard Schrieffer-Wolff transformation

\[
\tilde{H} = e^A H e^{-A}
\]

\[
\approx H_0 + H_1 + [A, H_0] + \frac{1}{2} [A, [A, H_0]],
\]

where the operator \( A \) (with \( A^\dagger = -A \)) is assumed to have a perturbative expansion in \( g \), i.e., \( A = 0 + \mathcal{O}(g) + \ldots \). By choosing

\[
[A, H_0] = -H_1,
\]

one obtains a Hamiltonian \( \tilde{H} \) without linear coupling in \( g \),

\[
\tilde{H} \approx H_0 + \frac{1}{2} [A, H_1].
\]

For the Hamiltonian given in Eq.(E2), the condition in Eq.(E7) is fulfilled by the choice

\[
A = \frac{g}{\Delta} \left( a S^+ - a^\dagger S^- \right),
\]

which yields the Hamiltonian

\[
\tilde{H} \approx \left( \Delta + \frac{g^2}{\Delta} \right) S^z + \frac{g^2}{\Delta} \left( S_1^+ S_2^- + S_1^- S_2^+ \right).
\]

Here, the last two terms describe a cavity-state dependent dispersive shift of the qubit transition frequencies and spin-spin coupling via virtual occupation of the cavity mode, respectively. The strength of the effective spin-spin coupling is given by

\[
geff = \frac{g^2}{\Delta} = \frac{\epsilon}{\sqrt{n_{th}} g},
\]

where we have set \( \sqrt{n_{th}} g/\Delta = \epsilon \ll 1 \) in order to reach the regime of validity for Eq.(E10), given by

\[
\sqrt{n_{th}} g \ll \Delta \ll \omega_c.
\]

By transforming the Hamiltonian given in Eq.(E10) back into the lab-frame, we recover the result presented in Ref.[26], namely

\[
H \approx \left[ \omega_c + 2 \frac{g^2}{\Delta} \left( S_1^+ + S_2^+ \right) \right] a^\dagger a + \left( \omega_q + \frac{g^2}{\Delta} \right) (S_1^+ + S_2^-) + \frac{g^2}{\Delta} \left( S_1^+ S_2^- + S_1^- S_2^+ \right).
\]

Here, spins and cavity mode are still coupled by the ac Stark shift term \( \sim a^\dagger a \). Accordingly, one obtains an effective pure spin Hamiltonian with flip-flop interactions provided that one can neglect any fluctuations of the photon number \( a^\dagger a \to \bar{n} = \langle a^\dagger a \rangle \), where \( \bar{n} \) is the average number of photons in the cavity mode [30].
Since the operator $S^z a^\dagger a$ in Eq. (E10) has an integer spectrum, one may wonder whether for stroboscopic times the spins disentangle from the resonator mode as well. Thus, let us consider the full time evolution generated by Eq. (E1)

\[ e^{-iHt} = e^{-iU^\dagger RU} = U^\dagger e^{-iHt} U \]  
\[ \approx U^\dagger \left[ \exp \left( -i t \left( \delta + \delta a^\dagger a \right) S^z \right) - i gt \left( S_1^z S_2^- + S_1^- S_2^z \right) \right] U, \]

with $U = \exp (A)$, $\delta = \Delta + g^2/\Delta$, $\tilde{\delta} = 2g^2/\Delta$ and $\tilde{g} = g^2/\Delta$. Note that Eq. (E15) is an approximate statement, relying on a perturbative expansion in the coupling $g$.

For stroboscopic times $\tilde{\delta}t = 2\pi m$, $e^{-i\tilde{\delta}t S^z a^\dagger a} = 1$, yielding

\[ e^{-iHt} \approx U^\dagger e^{-iH_{\text{spin}}t} U, \]

where $H_{\text{spin}} = \delta S^z + \tilde{g} (S_1^z S_2^- + S_1^- S_2^z)$ is a pure spin Hamiltonian, without any coupling to the resonator mode. However, in contrast to our scheme presented in the main text, the full time evolution does not reduce to a pure spin problem, since the Schrieffer-Wolff transformation $U = \exp \left[ \frac{g}{2} (a S^- - a^\dagger S^+) \right]$ does not commute with $e^{-iH_{\text{spin}}t}$, but rather entangles the qubits with the resonator mode.

Appendix F: Schrieffer-Wolff Transformation

If one restricts oneself to the regime $g \ll \omega_c$, the result stated in Eqn. (6) may also be derived in the perturbative framework of a Schrieffer-Wolff transformation. For concreteness, assuming $\omega_q = 0$, we consider the Hamiltonian

\[ H = \omega_c a^\dagger a + g S^z \otimes (a + a^\dagger), \]

where $S^z = \sum_i \eta_i^2 \sigma_i^z$ is a collective operator. In the following, and contrary to our general analysis in the main text, we restrict ourselves to the regime where the spin-resonator coupling $V$ can be treated perturbatively with respect to $H_0$, that is $g \ll \omega_c$. Performing a Schrieffer-Wolff transformation $\hat{H} = e^{A} H e^{-A}$ as presented in Sec. E, with $A = -\frac{g}{\omega_c} S^z (a - a^\dagger)$, we obtain an effective Hamiltonian $\hat{H}$ where the slow subspace is decoupled from the fast subspace up to second order in $g$. Explicitly it reads [compare Eq. (5)]

\[ \hat{H} \approx \omega_c a^\dagger a - \frac{g^2}{2 \omega_c} S^2_x. \]

Appendix G: Non-Zero Qubit Level Splitting

In our derivation of Eq. (5), starting from the generic spin-resonator Hamiltonian given in Eq. (1), we have assumed $\omega_q = 0$. As demonstrated also numerically in Section K below, small level splittings with $\omega_q \approx 0.2 \omega_c$ may still be tolerated without a significant loss in the amount of generated entanglement and the fidelity with the maximally entangled target state.

In this Appendix we investigate analytically the effects associated with a finite splitting $\omega_q > 0$. In this case, Eq. (3) can be generalized straightforwardly to

\[ H = U [\omega_c a^\dagger a - \frac{g^2}{2 \omega_c} S^2 + \frac{\omega_q}{g} \hat{S}^z] U^\dagger, \]

where $\hat{S}^z = U^\dagger S^z U$, with $U = \exp \left[ \frac{g}{\omega_c} S (a - a^\dagger) \right]$. In what follows, we restrict ourselves to the (experimentally) most relevant regime where $\mu = g/\omega_c \ll 1$, which allows for a simple perturbative expansion. Expansion in the small parameter $\mu$ yields

\[ \hat{S}^z \approx S^z - \mu (a - a^\dagger) [S, S^z] + \frac{\mu^2}{2} (a - a^\dagger)^2 [S, [S, S^z]]. \]

Specifically, for $S = \sum_i \sigma_i^z$ (as considered in the main text) we then obtain

\[ \hat{S}^z \approx S^z + 2i \frac{g}{\omega_c} S^y (a - a^\dagger) + 2 \left( \frac{g}{\omega_c} \right)^2 S^z (a - a^\dagger)^2, \]

which leads to an additional (undesired) contribution in Eq. (G1) of the form

\[ \frac{\omega_q}{2} \hat{S}^z \approx \frac{\omega_q}{2} S^z + \epsilon \left[ ig S^y (a - a^\dagger) + \frac{g^2}{\omega_c} S^z (a - a^\dagger)^2 \right]. \]

Here, in contrast to the ideal Hamiltonian $H_0$ in Eq. (G1) the spins are not decoupled from the (hot) resonator mode. However, apart from being detuned by at least $\omega_c - \omega_q$, the undesired terms—that lead to entanglement of the spins with the (hot) resonator mode—are suppressed by the small parameter $\epsilon = \omega_q/\omega_c \ll 1$. In the limit $\omega_q \to 0$ ($\epsilon \to 0$) we recover the ideal dynamics.

Appendix H: Errors due to Non-Zero Qubit-Level Splitting

In this Appendix we analyze errors induced by a non-zero qubit level splitting ($\omega_q/\omega_c > 0$). In the case of longitudinal spin-resonator coupling, we show that controlled phase gates can be implemented (as described in the main text for $\omega_q = 0$), even in the presence of non-zero and inhomogeneous qubit level splittings ($\omega_q > 0$), when applying either fast local single qubit gates (to correct the effect of known $\omega_q \neq 0$) or standard spin-echo
techniques (to compensate unknown detunings); see section H1. Therefore, for longitudinal spin-resonator coupling, our approach yields a high-fidelity hot gate, that is independent of the qubit level splitting \( \omega_q/\omega_c \geq 0 \). As detailed in section H2, this is not the case for transversal coupling, where \( \omega_q \neq 0 \) causes second order errors, which, however, are suppressed in certain decoherence-free subspaces. Thus, as opposed to the limiting regime where \( \omega_q = 0 \), the distinction between longitudinal and transversal spin-resonator coupling indeed becomes meaningful.

The model.—In the absence of other error sources (\( \kappa = \Gamma = 0 \)), the system’s dynamics are governed by the Hamiltonian

\[
H = H_0 + V, \\
H_0 = \omega_0 a^\dagger a + g S \otimes (a + a^\dagger), \\
V = \frac{\omega_q}{2} S_z,
\]

with \( S^2 = \sum_i \sigma_i^2 \) and \( S = \sum_{\alpha=x,y,z} \eta_\alpha^\alpha \sigma_\alpha^\alpha \). Below, we will set \( S^\alpha = S_\alpha \) (\( \alpha = x, z \)) interchangeably. Also, note that \( S^x, S^z \) as defined here refer to the usual spin operators multiplied by 2.

1. Longitudinal Spin-Resonator Coupling

Controlled phase gate.—Let us first focus on the case of longitudinal spin-resonator coupling, where \( S = \sum_i \sigma_i^z = S^2 \) and accordingly \( [H_0, V] = 0 \). In this scenario, controlled phase gates can be implemented (as described in the main text for \( \omega_q = 0 \)), even in the presence of non-zero qubit level splittings \( \omega_q > 0 \), when applying either fast local single qubit phase-gates (to correct the effect of known \( \omega_q \neq 0 \)) or standard spin-echo techniques (to compensate unknown detunings). By flipping the qubits (for example) halfway the evolution and at the end of the gate, the effect of \( V \) is canceled exactly. Denoting such a global flip of all qubits around the axis \( \alpha = x, y, z \) as \( U_\alpha(\varphi) = \exp[-i\varphi/2\alpha^\alpha] \ldots \exp[-i\varphi/2\alpha^N] = \exp[-i\varphi/2 \sum \sigma^\alpha_i] \), for two qubits the full evolution (in the computational basis \( \{00\}, \{10\}, \{01\}, \{11\} \)), intertwined by spin echo pulses, reads

\[
U(2t_m) = U_x(\pi) e^{-iHt_m} U_x(\pi) e^{-iHt_m},
\]

with \( \phi = 16\pi m\mu^2 \). The gate \( U(2t_m) \) is independent of the resonator mode and, as a consequence of the spin-echo \( \pi \)-pulses \( U_x(\pi) \), independent of \( \omega_q \); accordingly, the qubit level splittings do not have to be necessarily small. When complementing the propagator \( U(2t_m) \) with local unitaries, such that \( |0\rangle_i \to e^{-i\phi/2} |0\rangle_i \) and \( |1\rangle_i \to e^{i\phi/2} |1\rangle_i \), we obtain

\[
U_{\text{Cphase}} = U_x(-\phi) U_x(\pi) e^{-iHt_m} U_x(\pi) e^{-iHt_m},
\]

which yields a controlled phase gate for \( \phi = \pi/2 \) (corresponding to a gate time \( t_{\text{max}} = \pi/16\mu a \)), that is insensitive to the qubit level splittings \( \omega_q > 0 \).

For longitudinal spin-resonator coupling, Eq.(5) of the main text simply reads

\[
e^{-iHt_m} = \exp \left[ i2\pi m\mu^2 \hat{S}^2 \right], \tag{H8}
\]

with (the generalized expression) \( \hat{S}^2 = S^2 - (\omega_q/2\Omega_{\text{eff}}) S_z \), where \( S = \sum_i \eta_\alpha^\alpha \sigma_\alpha^\alpha \), while the operator \( S_z \) can also be generalized to account for possible inhomogeneities in the qubit level splittings (with \( \omega_q, i = \delta_i \omega_q \)), i.e. \( S^2 \to \sum_i \delta_i \sigma_i^z \). This gate differs from the ideal one \( \exp \left[ i2\pi m\mu^2 \hat{S}^2 \right] \) only by the local phases \( \exp[-it_m(\omega_q/2)S^z] \) and thus has the same computational power.

2. Transversal Spin-Resonator Coupling

Transversal spin-resonator coupling.—In the following we turn to systems with transversal spin resonator coupling, where \( S = S^x = \sum_i \sigma_i^x \). In this case, the theoretical treatment is more involved as compared to our previous discussion on longitudinal spin resonator coupling, because the ideal free evolution does not commute with the perturbation \( [H_0, V] \neq 0 \). We use perturbative techniques to derive an analytic expression for the error \( \xi_\epsilon \) induced by non-zero qubit splittings \( \omega_q > 0 \). For the sake of readability, here we restrict ourselves to two qubits, while our analysis can be generalized readily to more than two qubits.

Perturbative series.—Up to second order in the perturbation \( V \), the unitary evolution operator associated with \( H \) is approximately given by

\[
U(t) \approx e^{-iH_0 t} \left[ 1 - i \int_0^t d\tau \hat{V}(\tau) \\
- \int_0^t d\tau_1 \int_0^{\tau_1} d\tau_2 \hat{V}(\tau_2) \hat{V}(\tau_1) \right], \tag{H9}
\]

with

\[
\hat{V}(\tau) = e^{iH_0 \tau} V e^{-iH_0 \tau}. \tag{H10}
\]

Initially, the resonator mode is assumed to be in a thermal state \( \rho_{\text{th}} = \rho_{\text{th}}(T) = Z^{-1} \exp[-\beta \omega_q a^\dagger a] \). Then, starting from the initial state \( \rho(0) = \varphi(0) \otimes \rho_{\text{th}} \), the system (considering both spin and resonator degrees of freedom) evolves as

\[
\rho(t) = U(t) \varphi(0) \rho_{\text{th}} U^\dagger(t). \tag{H11}
\]

Inserting the perturbative expansion given in Eq.(H9),
up to second order in $V$ we obtain
\[
\rho(t) \approx e^{-iH_0 t}\left\{\rho(0) - i \int_0^t d\tau \left[\hat{V}(\tau), \rho(0)\right]\right. \\
+ \left. \int_0^t d\tau \int_0^{\tau'} d\tau' \hat{V}(\tau') \rho(0) \hat{V}(\tau)\right\}
\]

Eigensystem of unperturbed Hamiltonian.—In the first step, it is instructive to find the eigensystem of $H_0$. Following the same strategy as outlined in the main text, $H_0$ can be written as
\[
H_0 = D^\dagger (\mu S^z) \left[\omega_c a^\dagger a - g_{\text{eff}} S_z^2\right] D(\mu S^z),
\]
where $\mu = g/\omega_c$, $g_{\text{eff}} = g^2/\omega_c = \mu^2 \omega_c$ and $D(a) = \exp[\alpha a^\dagger - \alpha^* a]$ is a displacement operator. Accordingly, the eigensystem of $H_0$ is found to be
\[
\tilde{H}_0 |n, \sigma_z \rangle = E_{n,s} |n, \sigma_z \rangle,
\]
where the eigenvectors are given by product states of spins aligned along the transversal direction $x$ and displaced resonator states with a displacement proportional to the total spin projection $s$ along $x$,
\[
|n, \sigma_z \rangle = D^\dagger (\mu s) |n\rangle \otimes |\sigma_z \rangle,
\]
with $s = s^+_x + s^+_z$, $S^x |\sigma_z \rangle = (s^+_x + s^+_z) |\sigma_z \rangle$ and $|n\rangle$ denoting the usual Fock states. The corresponding eigenenergies
\[
E_{n,s} = n \omega_c - s^2 g_{\text{eff}},
\]
refer to manifolds with fixed resonator excitation number $n = 0, 1, 2, \ldots$ and two-qubit spin states with a resonator-induced splitting of $4g_{\text{eff}}$ between the states $\{|\uparrow x, \downarrow z\rangle, |\downarrow x, \uparrow z\rangle\}$ with $s^2 = 0$ and $\{|\uparrow x, \uparrow z\rangle, |\downarrow x, \downarrow z\rangle\}$ with $s^2 = 4$, respectively.

Perturbation in the interaction picture.—In the following we focus on the perturbative regime where the perturbation $\sim \omega_q$ is small compared to the resonator-induced splitting of $S^z$-eigenstates, that is $\omega_q \ll 8g_{\text{eff}} = 8\mu^2 \omega_c$. Rewriting the perturbation in the unperturbed eigenbasis yields
\[
V = \sum_{n,s} \sum_{\sigma_z, \sigma_z'} \langle n'|D[\mu(s' - s)]|n\rangle \langle \sigma_z'|V|\sigma_z\rangle |n', \sigma_z'\rangle \langle n|, \sigma_z |n\rangle.
\]
Using the relation [62]
\[
\langle m|D[\alpha]|n\rangle = \sqrt{\frac{m!}{m!}} \alpha^{m-n} e^{-|\alpha|^2/2} L_{n-m}^{(m-n)}(|\alpha|^2),
\]
with $L_{n-m}^{(m-n)}$ denoting the associated Laguerre polynomials, in the experimentally most relevant regime of weak spin-resonator coupling (that is, $\mu \ll 1$) we can neglect the off-diagonal contributions where $n \neq m$, since eigenstates with different boson number are very weakly coupled ($\sim \omega_q d^{n-m}$) and far off-resonance ($\omega_q \ll 8g_{\text{eff}} \ll \omega_c$), with rapidly decaying contributions as the number difference increases. In this limit, the perturbation in the interaction picture [compare Eq.(H10)] reads
\[
\hat{V}(\tau) \approx \hat{V}_q(\tau) \otimes \sum_n \chi_n(\mu) |n\rangle \langle n|,
\]
where
\[
\chi_n(\mu) = \langle n|D[\pm 2\mu]|n\rangle = e^{-2\mu^2} L_{n-0}^{(0)}(4\mu^2),
\]
Since the perturbation $V \sim S^z$ is purely off-diagonal in the $S^z$ eigenbasis, the operator
\[
Q = |\uparrow z\uparrow z\rangle \langle \downarrow z\downarrow z| + |\downarrow z\uparrow z\rangle \langle \uparrow z\downarrow z| \\
+ |\uparrow z\downarrow z\rangle \langle \downarrow z\uparrow z| + |\downarrow z\downarrow z\rangle \langle \uparrow z\uparrow z|,
\]
describes only transitions from the $s = \pm 2$ subspace to the $s = 0$ subspace (and vice versa for the Hermitian conjugate operator $Q^\dagger$), which in the interaction picture underlying Eq.(H20) rotate with the corresponding transition frequency $\pm 4g_{\text{eff}}$. While Eq.(H19) is purely off-diagonal in spin-space, in the limit $\mu \ll 1$ it is (approximately) diagonal in the excitation number $|n\rangle$, as the coupling $V$ between different $n$-subspaces is strongly damped by the corresponding large energy splitting $\sim \omega_c$.

Quasi-decoherence-free subspace.—In our numerical simulations, the initial qubit states have been chosen to be aligned along the $z$-direction, defining the computational basis states and corresponding to eigenstates of the perturbation $V \sim S^z$. Therefore, it is didactic to rewrite $\hat{V}(\tau)$ in the eigenbasis of $S^z$. With $|\uparrow z\rangle = (|\uparrow z\rangle + |\downarrow z\rangle)/\sqrt{2}$, and $|\downarrow z\rangle = (|\uparrow z\rangle - |\downarrow z\rangle)/\sqrt{2}$, we obtain
\[
Q = |\uparrow z\uparrow z\rangle \langle \uparrow z\uparrow z| - |\downarrow z\downarrow z\rangle \langle \downarrow z\downarrow z| \\
+ |\uparrow z\downarrow z\rangle \langle \downarrow z\uparrow z| - |\downarrow z\uparrow z\rangle \langle \uparrow z\downarrow z|.\]
As can be seen readily from this expression, the subspace $\{|\uparrow z\uparrow z\rangle, |\downarrow z\downarrow z\rangle\}$ with $S^z = 0$ defines a decoherence-free subspace, since $Q$ and $Q^\dagger$ [and therefore $\hat{V}(\tau)$] vanish on this subspace, with $Q|\uparrow z\uparrow z\rangle = Q|\downarrow z\downarrow z\rangle = 0$. In the following this finding is elaborated in more detail: To do so, we first rewrite $\hat{V}(\tau)$ as
\[
\hat{V}(\tau) = \frac{\omega_q}{2} D^\dagger(\mu S^z) e^{i\omega_c a^\dagger a t} e^{-ig_{\text{eff}} \tau S^z} D(\mu S^z) S^z \\
\times D^\dagger(\mu S^z) e^{-i\omega_c a^\dagger a t} e^{ig_{\text{eff}} \tau S^z} D(\mu S^z).
\]
states in the spin-eigenbasis of \( H_0 \) as
\[
\begin{align*}
|T^z_+\rangle &= |\uparrow_z \uparrow_x\rangle, \\
|T^z_0\rangle &= (|\uparrow_z \downarrow_x\rangle + |\downarrow_z \uparrow_x\rangle)/\sqrt{2}, \\
|T^z_-\rangle &= |\downarrow_z \downarrow_x\rangle, \\
|S^z\rangle &= (|\uparrow_z \downarrow_x\rangle - |\downarrow_z \uparrow_x\rangle)/\sqrt{2},
\end{align*}
\] (H25)

the (by definition) computational basis states (taken as initial states in our numerical simulations) are given by
\[
\begin{align*}
|\uparrow_z \uparrow_x\rangle &= \frac{1}{2} \left[ |T^z_+\rangle + \sqrt{2} |T^z_0\rangle + |T^z_-\rangle \right], \\
|\uparrow_z \downarrow_x\rangle &= \frac{1}{2} \left[ |T^z_+\rangle - \sqrt{2} |S^z\rangle - |T^z_-\rangle \right], \\
|\downarrow_z \uparrow_x\rangle &= \frac{1}{2} \left[ |T^z_+\rangle + \sqrt{2} |S^z\rangle - |T^z_-\rangle \right], \\
|\downarrow_z \downarrow_x\rangle &= \frac{1}{2} \left[ |T^z_+\rangle - \sqrt{2} |T^z_0\rangle + |T^z_-\rangle \right].
\end{align*}
\] (H29)

For a general resonator state \(|\text{cav}\rangle\), the first-order error term will be proportional to
\[
\hat{V}\langle \tau | T^z_+ | \text{cav}\rangle = \frac{\omega_g}{\sqrt{2}} e^{i4g_{\text{eff}} \tau} | T^z_0\rangle \otimes e^{i\omega_z a^\dagger a \tau} D^\dagger(2\mu)e^{-i\omega_z a^\dagger a \tau} D(2\mu) | \text{cav}\rangle,
\] (H33)
\[
\hat{V}\langle \tau | T^z_0 | \text{cav}\rangle = \frac{\omega_g}{\sqrt{2}} e^{-i4g_{\text{eff}} \tau} \left[ |T^z_+\rangle \otimes D^\dagger(2\mu)e^{i\omega_z a^\dagger a \tau} D(2\mu)e^{-i\omega_z a^\dagger a \tau} | \text{cav}\rangle + |T^z_-\rangle \otimes D^\dagger(-2\mu)e^{i\omega_z a^\dagger a \tau} D(-2\mu)e^{-i\omega_z a^\dagger a \tau} | \text{cav}\rangle \right],
\] (H34)
\[
\hat{V}\langle \tau | T^z_- | \text{cav}\rangle = \frac{\omega_g}{\sqrt{2}} e^{i4g_{\text{eff}} \tau} | T^z_0\rangle \otimes e^{i\omega_z a^\dagger a \tau} D(2\mu)e^{-i\omega_z a^\dagger a \tau} D(-2\mu) | \text{cav}\rangle,
\] (H35)
\[
\hat{V}\langle \tau | S^z | \text{cav}\rangle = 0.
\] (H36)

In the spirit of our previous discussion [recall Eq.(H18) with \(D^\dagger(\alpha) = D(-\alpha)\)], these exact statements can be simplified in the limit \(\mu \ll 1\) as
\[
e^{i\omega_z a^\dagger a \tau} D^\dagger(\pm2\mu)e^{-i\omega_z a^\dagger a \tau} = \sum_{n,n'} e^{i\omega_z \tau(n'-n)} \langle n' | D^\dagger(\pm2\mu) | n\rangle \langle n| n' \rangle,
\] (H37)
\[
\approx \sum_n \chi_n(\mu) | n\rangle \langle n|,
\] (H38)
yielding the approximate results [for a Fock state \(|\text{cav}\rangle = |n\rangle\)]
\[
\hat{V}\langle \tau | T^z_+ | n\rangle \approx \frac{\omega_g}{\sqrt{2}} e^{i4g_{\text{eff}} \tau} \chi_n^2(\mu) | T^z_0\rangle | n\rangle,
\] (H39)
\[
\hat{V}\langle \tau | T^z_0 | n\rangle \approx \frac{\omega_g}{\sqrt{2}} e^{-i4g_{\text{eff}} \tau} \chi_n^2(\mu) \left[ |T^z_+\rangle + |T^z_-\rangle \right] | n\rangle,
\] (H40)
\[
\hat{V}\langle \tau | T^z_- | n\rangle \approx \frac{\omega_g}{\sqrt{2}} e^{i4g_{\text{eff}} \tau} \chi_n^2(\mu) | T^z_0\rangle | n\rangle.
\] (H41)

With these (approximate) relations, one can readily verify \(\hat{V}\langle \tau | \uparrow_z \downarrow_x | n\rangle \approx 0\) and \(\hat{V}\langle \tau | \downarrow_z \uparrow_x | n\rangle \approx 0\), in agreement with our result based on Eq.(H23), while the subspace \(\{|\uparrow_z \uparrow_x\rangle, |\downarrow_z \downarrow_x\rangle\}\) is directly affected by the perturbation \(\hat{V}(\tau)\). As long as transitions between different \(n\)-subspaces can be neglected, the bosonic part of the Hamiltonian can be ignored and the free part of the Hamiltonian reduces to \(H_0 \approx -g_{\text{eff}} S_z^2\). Then, since the perturbation \(V = (\omega_g/2)S_z^2\) leaves the subspace \(\{|\uparrow_z \downarrow_x\rangle, |\downarrow_z \uparrow_x\rangle\}\) invariant, \(V\) cannot induce errors, since it vanishes on this subspace. As a perspective, this finding opens up the possibility to define a logical qubit in
we have introduced the second-order contribution where we have used that first-order terms vanish; more-

lytic expression for the splitting-induced error \( \xi_q \), in the following we derive an approximate ana-
satisfied). The latter depends on both the spin-resonator coupling \( \mu = g/\omega_c \) and temperature \( T \) (with \( \beta = 1/k_B T \)) and can be readily evaluated numerically. After some manipulations, we then arrive at an analytic expression for the error \( \xi_q = 1 - \mathcal{F}(t_{\text{max}}) \) at the (nominally) optimal time \( t_{\text{max}} = \pi/8g_{\text{eff}} \).

showing a quadratic scaling with the splitting \( \sim \omega_q^2 \). In the last step, we have introduced the pre-factor \( \alpha_q = \mathcal{Y}_q (\mu, k_B T) / (16 \mu^4) \).

Numerical results.—As shown in Fig.10, we have nu-
merically verified our analytical results (as discussed above): (i) The error \( \xi_q \) scales quadratically with the qubit splitting, i.e., \( \xi_q \sim (\omega_q/\omega_c)^2 \), with (ii) a numerical pre-factor \( \alpha_q \) depending on both the spin-resonator coupling \( g \) and temperature \( T \), and (iii) (all other parameters equal) the error \( \xi_q \) is found to be significantly smaller for initial states in the quasi-decoherence-free subspace \( \{|\uparrow_{z\downarrow}\rangle, |\downarrow_{z\uparrow}\rangle\} \) than for initial qubit states in the orthogonal subspace \( \{|\uparrow_{z\uparrow}\rangle, |\downarrow_{z\downarrow}\rangle\} \).

Appendix I: SAW-based Spin-Resonator System

Here, we provide further details on how to implement experimental candidate systems governed by the class of Hamiltonians given in Eq.(1), using quantum dots embedded in high-quality surface acoustic wave (SAW) resonators [46, 47]. For similar considerations based on (for example) transmission-line resonators or nanomechanical oscillators, we refer to Refs.[29] and [50], respectively.

Charge qubit.—A single electron in a double quantum dot (DQD) coupled to a SAW resonator can be described by

\[
H_{\text{charge}} = \frac{\epsilon}{2} \sigma^z + t_e \sigma^x + \omega_c a^\dagger a + g_{\text{ch}} \sigma^z \otimes (a + a^\dagger),
\]  

where \( \epsilon \) is the interdot detuning parameter, \( t_e \) the tunnel coupling between the dots, \( g_{\text{ch}} = e\phi_0 F(kd) \sin (kd/2) \) the bare single-phonon coupling strength (assuming a sine-like mode function of the piezoelectric potential, with a node tuned between the two dots separated by a distance \( l \)), and the (orbital) Pauli operators are defined as \( \sigma^z = |L\rangle \langle L| - |R\rangle \langle R| \) and \( \sigma^x = |L\rangle \langle R| + |R\rangle \langle L| \), respectively [46]. In our expression for \( g_{\text{ch}} \), \( \epsilon \) refers to the electron’s charge, and \( \phi_0 \) to the piezoelectric potential associated with a single SAW phonon; the decay of the SAW resonator mode into the bulk is captured by the factor \( F(kd) \), where \( d \) is the distance between the DQD and the surface and \( k = 2\pi/\lambda_c \), the wavevector of the resonator mode [46]. In the computational basis, where the dot Hamiltonian \( H_{\text{dot}} = \frac{\epsilon}{2} \sigma^z + t_e \sigma^x \) is diagonal, with
the electronic eigenstates

$$|+\rangle = \cos \theta |L\rangle + \sin \theta |R\rangle, \quad (I2)$$

$$|\rangle = -\sin \theta |L\rangle + \cos \theta |R\rangle, \quad (I3)$$

where the mixing angle is given by $\tan \theta = 2t_c/ (\epsilon + \Omega)$, $\Omega = \sqrt{\epsilon^2 + 4t_c^2}$, the spin-resonator Hamiltonian given in Eq.(II) can be rewritten as

$$H_{\text{charge}} = \frac{\Omega}{2} S^z + \omega_c a^\dagger a + g^e S^x \otimes (a + a^\dagger)$$

$$+ g^s S^z \otimes (a + a^\dagger), \quad (I4)$$

where the Pauli operators in the logical qubit basis are $S^z = (|+\rangle \langle +| - |\rangle \langle \rangle)$, $S^x = (|+\rangle \langle +| + |\rangle \langle \rangle)$ and

$$g^e = g_{\text{ch}} \frac{2t_c}{\Omega}, \quad (I5)$$

$$g^s = -g_{\text{ch}} \frac{\epsilon}{\Omega}. \quad (I6)$$

In the last step, we have made use of the relations $2\sin \theta \cos \theta = \sin (2\theta) = 2t_c/\Omega$ and $\cos^2 \theta - \sin^2 \theta = \cos (2\theta) = \epsilon/\Omega$. In the limit where $\delta, g_{\text{ch}} \ll \omega_c$, with $\delta = \Omega - \omega_c$, one can perform a rotating-wave approximation yielding the standard Jaynes-Cummings Hamiltonian [35]. Finally, the spin-resonator Hamiltonian given in Eq.(I4) belongs to the general class of Hamiltonians defined in Eq.(I). In particular, at the charge degeneracy point $\epsilon = 0$, where $\sin \theta = \cos \theta = 1/\sqrt{2}$, the Hamiltonian given in Eq.(I4) reduces to

$$H_{\text{charge}} = t_c S^z + \omega_c a^\dagger a + g_{\text{ch}} S^z \otimes (a + a^\dagger). \quad (I7)$$

Accordingly, the (pseudo-) spin-resonator coupling is maximized at this charge-degeneracy point, i.e., when there is no bias between the two dots, and decreases as one moves away from this point [29, 32, 35].

**Coupling strength.**—Following Ref.[47], the single phonon coupling strength $g_{\text{ch}}$ may be expressed as

$$g_{\text{ch}} = c_{\text{ch}} = \frac{\alpha_{\text{eff}}}{\omega_c} \sqrt{\frac{\pi^2 \lambda}{V}}, \quad (I8)$$

where $V$ is the mode volume associated with the resonator mode and $\alpha_{\text{eff}} = \alpha K^2 c/v_s \epsilon_r$ is an effective fine-structure constant, defined in terms of the fine structure constant $\alpha \sim 1/137$, the (material-specific) electromechanical coupling coefficient $K^2$ (as a widely used measure to quantify the piezoelectric coupling strength), the speed of light $c$, the SAW speed of sound $v_s$ and the relative dielectric constant $\epsilon_r$. The coupling parameter $K^2$ describes piezoelectric stiffening and may be expressed as $K^2 = c_{14}/\epsilon_c$, where $c_{14}$, $\epsilon$, and $\epsilon_r$ represent to representative values of the piezoelectric, the elasticity and the dielectric tensor, respectively. Typical values for $\alpha_{\text{eff}}/\alpha$ range from $\alpha_{\text{eff}}/\alpha \sim 10$ for GaAs up to $\alpha_{\text{eff}}/\alpha \gtrsim 100$ for strongly piezoelectric materials such as LiNbO$_3$ or ZnO, underlining the potential of SAW based systems to reach the ultra-strong-coupling regime [47]. For a typical SAW penetration length $\sim 0.3\lambda$ close to the surface, Eq.(I8) further simplifies to $g_{\text{ch}}/\omega_c \approx (0.5 - 1.5) \sqrt{\pi^2 \lambda}/A$, where $A$ refers to the surface mode area. When expressing $\alpha_{\text{eff}}$ in terms of the fundamental material parameters, Eq.(I8) can be rewritten as

$$g_{\text{ch}} = \frac{c_{14}}{\epsilon_c} \sqrt{\frac{\pi^2 \lambda}{V}}. \quad (I9)$$

This estimate also follows from the expression given above, $g_{\text{ch}} = \epsilon \phi_0 F(kd) \sin (kd)/2$, with $\phi_0 \approx (\epsilon_{14}/\epsilon) \sqrt{2\rho \nu \omega_c}$ [46], close to the surface $F(kd) \approx 1$, and with $\sin (kd)/2 \approx kd/2$ for $kd \ll 1$ (in the spirit of circuit QED setups).

**Spin qubit.**—In the two-electron regime of a DQD, one can couple the effective dipole-moment of singlet-triplet circuit QED setups). The coupling is reduced by the admixture of the qubit’s states $\{|0\}, |1\rangle$ with the localized singlet $|\rangle = (|0\rangle |S_0\rangle)$. Again, for $\Omega \approx \omega_c$ and $\epsilon \ll \omega_c$, we recover the prototypical Jaynes-Cummings dynamics. Moreover, the spin-resonator Hamiltonian given in Eq.(I10) belongs to the general class of Hamiltonians defined in Eq.(I).

**Hot gate.**—For such a spin qubit a spin-resonator coupling strength of $g_{\text{sf}}/2\pi \equiv g^e/2\pi = (g_{\text{ch}}/2\pi) k_0 \kappa_n \approx 3.2\text{MHz} (g^e/2\pi \approx 0.64\text{MHz})$ has been predicted for typical parameters in GaAs [46]. For a typical resonator frequency $\omega_c/2\pi \approx 1.5\text{GHz}$, this amounts to a relative coupling strength $\mu_{\text{sp}} = g_{\text{sp}}/\omega_c \approx 0.2\%$ and an effective coupling $g_{\text{sf}}/2\pi = \mu_{\text{sp}} g_{\text{ch}}/2\pi \approx 65\text{kHz}$, which could be increased substantially by additionally depositing a strongly piezoelectric material such as LiNbO$_3$ or ZnO on the GaAs substrate [46, 47, 63]. The condition $\omega_c \gg \Omega$ can be satisfied by choosing the magnetic gradient $\Delta$ between the dots appropriately, $\Delta \lesssim 0.1\mu\text{eV}$. Recently, SAW resonators with quality-factors approaching $\sim 10^6$ have been realized experimentally [64]. Then, taking an optimistic quality-factor of $Q = 10^6$, according to the hot-gate requirement $k_BT \ll Q \times g_{\text{eff}}$, we find $T \ll 3.1\text{K}$; therefore, for spin qubits coupled to high-quality SAW-resonators, our scheme can tolerate temperatures approaching the Kelvin regime, where the thermal occupation number is much larger than one. For example, for $\omega_c/2\pi \approx (1.0 - 1.5)\text{GHz}$ and $T \approx 0.5\text{K}$, we have $n_{\text{th}} \approx 6.5 - 10$. The second requirement for small errors, $\Gamma \ll g_{\text{eff}}$, yields $\Gamma/2\pi \ll 65\text{kHz}$, which may be
satisfied in GaAs with recently demonstrated echo techniques, where decoherence timescales $T_2 \approx 1\text{ms}$ have been demonstrated [65]. Finally, with $\tilde{n}_{th}/Q \approx 10/10^6$ and $\Gamma/\omega_c \approx 1\text{kHz}/1.5\text{GHz}$, and using the relation $\xi \approx \alpha_\epsilon (\kappa/\omega_c) \tilde{n}_{th} + \alpha_\Gamma \Gamma/\omega_c$, we can estimate the overall error as $\xi \approx 4 \times 10^{-5} + 2.5 \times 10^{-2} \approx 2.5\%$, which is largely limited by dephasing-induced errors (for the parameters chosen here). Again, to counteract this source of error, a strongly piezoelectric material such as LiNbO$_3$ may be used on the GaAs substrate. Alternatively, one could also investigate silicon quantum dots: while this setup also requires a more sophisticated heterostructure including some piezoelectric layer, it should benefit from prolonged dephasing times $T_2^* > 100\mu\text{s}$ [58], which is not longer than the dephasing time $T_2$ quoted above for GaAs, but relaxes the need for dynamical decoupling.

Appendix J: Microscopic Derivation of the Noise Model

In this Appendix we provide a microscopic derivation of the Master equation given in Eq.(7) of our manuscript. Here, we focus on the relevant decoherence processes induced by coupling between the resonator mode and its environment and restrict ourselves to the regime of interest where $\omega_q \to 0$. Our analysis is built upon the master equation formalism, a tool widely used in quantum optics for studying the irreversible dynamics of a quantum system coupled to a macroscopic environment. We detail the assumptions of our approach and discuss in detail the relevant approximations.

1. The Model

We consider a generic linear coupling between the resonator mode and a set of independent harmonic oscillators (representing e.g. the modes of the free electromagnetic field), as described by the following textbook system-bath Hamiltonian

$$H = H_S + H_B + H_I,$$

$$H_S = \omega_c a^\dagger a + g S \otimes (a + a^\dagger),$$

$$H_B = \int_{\omega_c - \Delta B}^{\omega_c + \Delta B} d\omega \omega b^\dagger_\omega b_\omega,$$

$$H_I = \int_{\omega_c - \Delta B}^{\omega_c + \Delta B} d\omega \sqrt{\kappa(\omega)} \frac{\kappa(\omega)}{2\pi} (a^\dagger b_\omega + ab^\dagger_\omega),$$

where $b_\omega$ refer to bosonic bath operators obeying standard commutation relations with $[b_\omega, b^\dagger_\omega] = \delta (\omega - \omega')$ etc. and $\Delta B$ denotes the characteristic bandwidth of the bath [66–68]. Within a rotating-wave approximation, we have dropped all energy non-conserving terms, which is valid if the system’s characteristic frequency $\omega_c$ is the largest frequency in the problem [67]. The bandwidth $\Delta_B$ is the frequency range over which the system-bath coupling is valid; it is closely related to the characteristic memory or correlation time of the bath $\tau_c \sim \Delta_B^{-1}$, as can be readily seen from the relation

$$\int_{\omega_c - \Delta B}^{\omega_c + \Delta B} d\omega e^{-i\omega \tau} = 2\Delta_B e^{-i\omega_c \tau} \text{sinc} (\Delta_B \tau)$$

$$= 2\pi \delta_{\Delta_B}(\tau) e^{-i\omega_c \tau},$$

as it appears in the standard derivation of the Master equation presented below (if the spectral noise density $\kappa(\omega)$ and the thermal occupation number $\tilde{n}_{th}(\omega)$ are evaluated self-consistently at $\omega = \omega_c$). Here, the function $\delta_{\Delta_B}(\tau) = \pi^{-1} \Delta_B \text{sinc} (\Delta_B \tau)$ is a well-defined Dirac-like function with a maximal amplitude $\Delta_B/\pi$ at $\tau = 0$ and a width of the order of $\tau_c \sim 2\pi/\Delta_B$ [54]. Since the integral equals one, this function is an approximate delta function which tends to $\delta(\tau)$ in the so-called white-noise limit $\Delta_B \to \infty$ (that is, $\tau_c \to 0$). Intuitively, $\delta_{\Delta_B}(\tau)$ can be seen as a slowly-varying function (on the $\sim \omega_c^{-1}$ timescale) that effectively acts as a delta function on timescales of the system evolution (i.e., much slower than $1/\Delta_B$).

Typically, $\Delta_B \ll \omega_c$ is assumed [66, 67], but $\tau_c$ is still much shorter than the relevant timescales of the system dynamics $\tau_{\text{sys}}$ (other than the free rotation $\omega_c$), that is

$$\omega_c \gg \Delta_B \gg \tau_{\text{sys}}^{-1}.$$  

In this case, the bandwidth $\Delta_B$ can be much larger than the spin-resonator coupling strength $g$ (which implies $g\tau_c \ll 1$, as required for the standard master equation treatment discussed below), but still much smaller than the characteristic frequency $\omega_c$. The system-reservoir coupling is usually only valid within a bandwidth $2\Delta_B \ll \omega_c$, around $\omega_c$ [67]. Within this frequency range the coupling strength may be approximated by a constant value as $\kappa(\omega) \approx \kappa(\omega_c)$, as schematically depicted in Fig.11.
2. Microscopic Derivation of the Master Equation

Our analysis is based on the standard Born-Markov framework, where correlations between the system and the bath are neglected (on relevant timescales), since the bath is considered to be very large and the effect of the interaction with the (small) system is negligible. Within this standard Born-Markov approximation \cite{54,69}, in the interaction picture the system’s dynamics are described by

\[ \dot{\rho} = -\int_0^\infty d\tau \mathbb{T}_B \left\{ \hat{\mathcal{H}}_I (t), \left[ \hat{\mathcal{H}}_I (t - \tau), \dot{\rho} (t) \rho_B \right] \right\}, \] (J8)

where we have used the fact that the resonator annihilation operators transform as

\[ \tilde{a} (t) = e^{iH_B t} \tilde{a} e^{-iH_B t} = e^{-i\omega t} (a + \mu S) - \mu S, \] (J12)

while the bath operators transform simply as \( \tilde{b}_\omega (t) = e^{iH_B t} \tilde{b}_\omega e^{-iH_B t} = e^{-i\omega t} \tilde{b}_\omega \). Next, let us single out one term explicitly, but all other terms follow analogously. Using the thermal correlation functions as stated in Eq. (J9), we then obtain

\[ \mathbb{T}_B \left\{ \hat{\mathcal{1}} \right\} = \int_{\omega_c - \Delta_B}^{\omega_c + \Delta_B} d\omega \frac{\kappa (\omega)}{2\pi} \left\{ \tilde{n}_\text{th} (\omega) e^{-i\omega \tau} \left[ e^{i\omega t} (a^\dagger + \mu S) - \mu S \right] \tilde{\rho} (t) \right\} \] (J13)

and similar expressions for the remaining terms in Eq. (J8). In the next step, we perform the integration over the past, using the relation \cite{71}

\[ \int_0^\infty d\tau e^{\pm i(\omega_c - \omega)\tau} = \pi \delta (\omega_c - \omega) \pm iP \frac{1}{\omega_c - \omega}, \] (J14)

with \( P \) denoting Cauchy’s principal value, perform the integration over frequency, and within a rotating wave approximation (which is valid for the realistic parameter regime \( \mu \kappa (\omega_c) \tilde{n}_\text{th} (\omega_c) \sqrt{\tilde{n}_\text{th} (\omega_c)} \ll \omega_c \)) drop all fast oscillating terms \( \sim \exp [\pm i\omega_c t] \). After some simple manipulations, we then arrive at the master equation

\[ \dot{\tilde{\rho}} = \kappa (\omega_c) \left[ \tilde{n}_\text{th} (\omega_c) + 1 \right] D \left[ a + \mu S \right] \tilde{\rho} + \kappa (\omega_c) \tilde{n}_\text{th} (\omega_c) D \left[ a^\dagger + \mu S \right] \tilde{\rho} - i\Delta_c \left[ \left( a^\dagger + \mu S \right) (a + \mu S), \tilde{\rho} \right] + \gamma D \left[ S \right] \tilde{\rho} - i\Delta S \left[ S^2, \tilde{\rho} \right]. \] (J15)

Here, we have introduced the decay rate

\[ \gamma = \mu^2 \int_{\omega_c - \Delta_B}^{\omega_c + \Delta_B} d\omega \kappa (\omega) \left\{ 2\tilde{n}_\text{th} (\omega) + 1 \right\} \delta (\omega - 0) \] (J16)
which derives from the terms in Eq. (J13) rotating at zero frequency, and the Lamb-like energy shifts
\[
\Delta c = \int_{\omega - \Delta_B}^{\omega + \Delta_B} \kappa (\omega) \frac{1}{2\pi} \omega_{c} - \omega, \tag{J17}
\]
\[
\Delta S = \mu^2 \int_{\omega - \Delta_B}^{\omega + \Delta_B} \kappa (\omega) \frac{1}{2\pi} \omega, \tag{J18}
\]
In accordance with the frequency regime \((\omega_c \gg \Delta_B \gg \tau_{sys})\) discussed above, we assume the bandwidth \(\Delta_B\) to be large, but finite. In this case, the rate \(\gamma\) vanishes \((\gamma = 0)\), as the integration range does not cover the \(\delta\)-peak at \(\omega = 0\). Physically, the regime where the lower limit of the relevant frequency range \(\omega_c - \Delta_B\) does not extend all the way down to zero frequency amounts to the existence of a lower frequency cut-off \(\omega_{cut} = \omega_c - \Delta_B\). For example, such a lower frequency cut-off \(\omega_{cut}\) naturally arises in the context of a phonon bath where the existence of \(\omega_{cut} \sim \lambda_{cut}^{-1}\) is due to finite device dimensions (since a phonon wavelength \(\lambda\) larger than the device dimensions is not supported by this structure). Moreover, phonons with a wavelength much larger than the resonator are not able to resolve the resonator and simply represent a global shift of the resonance structure as a whole (and therefore do not linearly couple to the localized resonator mode). On the contrary, in the limit of infinite bandwidth \(\Delta_B \to \infty\), the decay rate \(\gamma\) (as well as the Lamb-like shifts \(\Delta c, \Delta S\)) will depend on the relevant reservoir spectral density \(
\kappa (\omega) / 2\pi = g^2 (\omega) D_{DOS} (\omega), \tag{J19}\n\)

often abbreviated as \(J(\omega) = \kappa (\omega) / 2\pi\) in the literature \[72\]. The spectral density \(J(\omega) = \sum_k |g_k|^2 \delta (\omega - \omega_k)\) encodes the features of the environment relevant for the reduced system description, and depends on both the environmental density of the modes \(D_{DOS}(\omega)\) and on how strongly the system couples to each mode \(\sim g(\omega)\). For concreteness, let us discuss two particular examples: (i) First, in quantum optical systems typically \(J(\omega) \sim \omega^n\) for a positive integer \(n\) \[70, 71\]; in particular, for coupling of a harmonic oscillator to the electromagnetic field in three dimensions in free space the spectral density scales as \(J(\omega) \sim \omega^3\) \[73\]. In this case, even in the absence of a lower frequency cut-off \(\omega_{cut}\), the rate \(\gamma\) vanishes, because \(\kappa (\omega) \bar{n}_{th}(\omega) \sim \omega^2 \to 0\) in the limit \(\omega \to 0\). (ii) Second, a prominent phenomenological ansatz frequently used in the literature is the so-called Caldeira-Leggett model, where \(J(\omega) \sim \omega^a \Omega_{cut}^{-1} e^{-\omega^2/\Delta_{cut}}\) for all \(\alpha > 0\) and some high-frequency cut-off \(\Omega_{cut}\) \[72\]. Environments with \(0 < \alpha < 1\) are referred to as sub-ohmic, while those corresponding to \(\alpha = 1\) and \(\alpha > 1\) are called ohmic and super-ohmic, respectively \[72\]. Within this Caldeira-Leggett model (and for \(\Delta_B \to \infty\)), the decay rate \(\gamma\) given in Eq. (J16) behaves for super-ohmic spectral densities with \(\alpha > 1\), becomes a constant for \(\alpha = 1\) and diverges for \(\alpha < 1\), since \(\bar{n}_{th}(\omega) \sim k_B T/\omega\) for \(k_B T \gg \omega\).

Here, we restrict our analysis to the regime where \(\gamma\) vanishes, either because of the existence of a lower frequency cut-off \(\omega_{cut} > 0\) or a spectral density with \(J(\omega) \sim \omega^\alpha (\alpha > 1)\), as discussed above. Moreover, following the standard treatment \[54, 74\] we neglect the Lamb shift \(\Delta S \sim \mu^2\) (typically, it is assumed that the Cauchy principal part of an integral of the spectral density is very small compared to the real part expressions \[69, 75\]), yielding the master equation
\[
\dot{\rho} = \kappa (\omega_c) \bar{n}_{th}(\omega_c) + 1 \mathcal{D} [a + \mu S] \rho + \kappa (\omega_c) \bar{n}_{th}(\omega_c) \mathcal{D} [a^\dagger + \mu S] \rho - i\Delta_c \left[ (a^\dagger + \mu S) (a + \mu S), \rho \right], \tag{J20}
\]
which (due to the interaction-mediated hybridization of spin and resonator degrees of freedom \(\sim g\)) displays correlated decay terms of both resonator and spin degrees of freedom, that are proportional to the effective rate \(\sim \kappa (\omega) \bar{n}_{th}(\omega)\) evaluated at the (large) characteristic system frequency \(\omega_c\). Using the relation
\[
e^{-iH_{st} t} (a + \mu S) e^{iH_{st} t} = e^{i\omega_{cut} t} (a + \mu S), \tag{J21}\]
the corresponding master equation in the Schrödinger picture is found to be
\[
\dot{\rho} = \kappa (\omega_c) \bar{n}_{th}(\omega_c) + 1 \mathcal{D} [a + \mu S] \rho + \kappa (\omega_c) \bar{n}_{th}(\omega_c) \mathcal{D} [a^\dagger + \mu S] \rho - i[H_s, \rho] - i\Delta_c \left[ (a^\dagger + \mu S) (a + \mu S), \rho \right]. \tag{J22}
\]
In what follows, we restrict our analysis to the experimentally most relevant regime of weak spin-resonator coupling where \(\mu \approx g/\omega_c \ll 1\). Within the corresponding approximation of independent rates of variation \[54\], the interactions with the environment are treated separately for spin and resonator degrees of freedom; in other words, they can approximately treated as independent entities and the terms (rates of variation) due to internal and dissipative dynamics are added independently. While for ultra-strong coupling the qubit-resonator system needs to be treated as a whole when studying its interaction with the environment \[74\], yielding irreversible dynamics through jumps between dressed states (rather than bare states), in the weak coupling regime we recover standard (quantum optical) dissipators, i.e.,
\[
\dot{\rho} = -i[H_s, \rho] + \kappa \bar{n}_{th}[1 + \mathcal{D} [a] \rho + \kappa \bar{n}_{th}] \mathcal{D} [a^\dagger] \tag{J23}\]
In the last step, we have set \(\kappa \equiv \kappa (\omega_c), \bar{n}_{th} \equiv \bar{n}_{th}(\omega_c)\) and dropped the energy shift \(\Delta_c\), which may be incorporated into a renormalized cavity frequency \(\omega_c \to \omega_c + \Delta_c\).

Note that the approximate replacement of the correlated dissipators by uncorrelated ones, that is \(\mathcal{D} [a + \mu S] \rho \to \mathcal{D} [a] \rho \) and \(\mathcal{D} [a^\dagger + \mu S] \rho \to \mathcal{D} [a^\dagger] \rho\), gives rise to a conservative error estimate for our hot gate. As can be shown analytically (compare Appendix L), the rethermalization-induced error \(\xi_c\) induced by independent decay terms as given in Eq. (J23) is twice as large as the one due to correlated decay terms. This statement has also been verified numerically; compare Tab. 1.
While Eq. (J23) is not rigorous (given the approximations made throughout its derivation), this type of noise model (with independent rather than correlated decay terms, and complemented by additional dissipators for the qubits) has been used widely to describe a great variety of relevant spin-resonator systems (in the regime of weak spin-resonator coupling for values up to \( \mu = g/\omega_c \lesssim 4\% \) [76]), ranging e.g. from superconducting qubits [25, 76] as well as quantum dots coupled to transmission line resonators [31, 37], to NV-center spins [49] or carbon nanotubes [77] coupled to nanomechanical oscillators. For example, in Refs. [31, 37] very good agreement with experimental results has been achieved for \( \mu \sim 1\% \).

We conclude this discussion with a final remark on low-frequency noise: As shown above, the existence of a low-frequency cut-off does exclude low-frequency contributions to resonator-mediated dephasing of the spins (since \( \gamma = 0 \)). Still, low-frequency noise (deriving for example from ambient nuclear spins [1]) may still couple directly to the qubits. In our model, this type of noise is captured by the dephasing rate \( \Gamma \), which may, however, be mitigated efficiently by simple spin-echo techniques.

### Appendix K: Additional Numerical Results

Here, we provide further detailed results based on the numerical simulation of the master equation given in Eq. (7). Just as in the main text, for all simulations shown below the initial state of the spin-resonator system has been chosen as \( \rho(0) = |\uparrow\uparrow\rangle \langle \uparrow\uparrow| \otimes \rho_{\text{th}}(T) \), with the cavity mode in the thermal state \( \rho_{\text{th}}(T) = Z^{-1} \exp[-\beta \omega_a a^\dagger a] \).

Apart from the state fidelity \( F \), we also quantify the logarithmic negativity \( E_N \) (which ranges between 0 for separable states to at maximum 1 for two maximally-entangled qubits) in order to quantify the entanglement between the two qubits.

**Periodic recurrences.**—First, as displayed in Fig. 12, we observe periodic recurrences of the maximally-entangling dynamics: For example, for \( g/\omega_c = 1/4 \) (as used in Fig. 12), ideally—apart from \( F = 1 \) at \( (\omega_c/2\pi)t = 1 \)—we find \( F = 1 \) again at \( (\omega_c/2\pi)t = 5 \), since \( U^f_R(m = 5, 1/4) = \exp[i\pi \sigma^x_1 \sigma^y_2] U^f_R(1, 1/4) = -U^f_R(1, 1/4) \). This statement holds provided that dephasing is negligible on the relevant timescale; compare the dashed curve in Fig. 12 which accounts for dephasing of the qubits.

**Non-zero level splitting.**—While our analytical treatment has assumed \( \omega_q = 0 \), in Fig. 13 we provide exemplary numerical results that explicitly account for a non-zero qubit level splitting \( \omega_q > 0 \), showing that the
proposed protocol can tolerate non-zero level splittings of the qubits $\omega_f/\omega_c \lesssim 0.1$, without a severe reduction in the fidelity of the protocol. Again, this numerical finding is corroborated in Fig.14. Here, it is shown explicitly that a strong entanglement reduction is observed once condition (8) is violated. Conversely, within the range of parameter values satisfying Eq.(8), the results are rather insensitive to the particular parameter values.

**Rethermalization-induced errors.**—As illustrated in Fig.15, we have numerically checked that (for small infidelities) the rethermalization induced error $\xi$, scales linearly with the effective rethermalization rate $\kappa_{\text{eff}} = \kappa_{\text{th}}$. Notably, as evidenced in Fig.15, the error is found to be independent of the spin-resonator coupling $g$. As demonstrated in in Sec. L, this numerical result can be corroborated analytically within a perturbative framework.

**Full error analysis.**—Similar to Fig.4(c) in the main text, in Fig.16 we provide numerical results that fully account for higher-order, correlated errors (beyond the linear error approximation). Here, we have chosen a temperature $k_B T/\omega_c = 4$, a factor two larger than the one used in Fig.4(c) in the main text. Still, if the rethermalization induced error is scaled in terms of the effective decay rate $\kappa_{\text{eff}} = \kappa_{\text{th}}$, we obtain (approximately) the same total error $\xi$, independently of the temperature $k_B T$, showing that the effective decay rate $\kappa_{\text{eff}} = \kappa_{\text{th}}$ captures well any temperature-related effects. This is evidenced numerically in Fig.16 which approximately coincides with the results displayed in Fig.4(c) in the main text and is line with our simple error estimate for rethermalization induced errors; compare Eq.(10) in the main text.

---

**Figure 14:** (color online). Logarithmic negativity $E_N$ for $k_B T/\omega_c = 1$ and different cavity quality factors: $Q = 10^5$ (solid blue), $Q = 10^2$ (dash-dotted blue), and $Q = 10$ (dashed magenta). A clear reduction of the maximum entanglement is observed, if the quality factor $Q$ is too low to satisfy the hot-gate requirement given in Eq.(8). Here, we have $g/\omega_c \times g/k_B T = 1/16 = 6.25 \times 10^{-2}$. The red (dotted) curve refers to $Q = 10^2$ and $\omega_f/\omega_c = 0.2$. Other numerical parameters: $g/\omega_c = 1/4$ and $\Gamma/\omega_c = 0$.

**Figure 15:** (color online). Error as a function of the effective rethermalization rate $\kappa_{\text{th}}$ for $g/\omega_c = 1/16$ (red squares), $g/\omega_c = 1/8$ (green triangles) and $g/\omega_c = 1/4$ (blue stars) and $g/\omega_c = 1/8$ (green triangles) and $g/\omega_c = 1/16$ (red squares). The dash-dotted line in cyan refer to linear fits, demonstrating a linear error scaling in the small error-regime ($\kappa_{\text{eff}}/g_{\text{th}} \ll 1$), which is independent of $\mu = g/\omega_c$. Accordingly, the error is larger for higher temperatures, but all temperature related effects are approximately captured by the thermal occupation number $n_{\text{th}}$. Other numerical parameters: $\Gamma = 0$ and $\omega_q = 0$.

**Figure 16:** (color online). Total error $\xi$ as a function of both the effective rethermalization rate $\sim \kappa/\omega_{\text{th}}$ and the spin dephasing rate $\sim \Gamma/\omega_c$ for $g/\omega_c = 1/16$, $k_B T/\omega_c = 4$ and $\omega_q = 0$.

**Timing errors.**—Finally, we consider errors (infidelities) due to limited timing accuracies. To do so, we take the average fidelity of our protocol $F$ within a certain timing window $\Delta t$ centered around the stroboscopic time $t_{\text{max}}$ for which maximum fidelity (minimal infidelity) is achieved; for example, in quantum dot systems timing accuracies $\Delta t$ of a few picoseconds have been demonstrated experimentally [78]. For $g/2\pi = 10\text{MHz}$
and \(\omega_c/2\pi = 160\text{MHz}\) (that is, \(\mu = g/\omega_c = 1/16\)) as used in the main text, the pulse time lies in the microsecond regime (\(t_{\text{max}} = \pi/8\text{GHz} \approx 0.2\text{µs}\)), for which \(\Delta t \approx 1\text{ps}\) is feasible; for this relatively long pulse, the relative time jitter is well below the percent level, i.e., \((\omega_c/2\pi)\Delta t \approx 10^{-4}\). Based on our numerical simulations, we make the following observations: (i) As demonstrated in Fig.17, we find an average error scaling linearly with \(\sim \bar{n}_{\text{th}}\), that is \(\xi = 1 - \bar{F} \sim \bar{n}_{\text{th}}\). (ii) More precisely, the error expressions given in the main text can be generalized to

\[
\bar{\xi} = \bar{\alpha}_c \frac{\kappa}{\omega_c} \bar{n}_{\text{th}} + \bar{\alpha}_t \frac{\Gamma}{\omega_c} + \bar{\beta}_c + \bar{\beta}_t. \tag{K1}
\]

Here, the unit-less quantities \(\bar{\alpha}_c, \bar{\beta}_c\), for \(\gamma = \kappa, \Gamma\) depend on the timing window \(\Delta t\). For example, for \(g/\omega_c = 1/16\) and \((\omega_c/2\pi)\Delta t = 5\%\), we then extract \(\bar{\alpha}_c \approx 4.03, \bar{\beta}_c \approx 2.2 \times 10^{-4}\), \(\bar{\alpha}_t \approx 24.22\) and \(\bar{\beta}_t \approx 5.1 \times 10^{-4}\). (iii) As shown in Fig.17, for the experimentally most relevant regime where \((\omega_c/2\pi)\Delta t \ll 1\) (such that the timing window covers a small range of the oscillations only), this error is found to decrease for a smaller spin-resonator coupling strength \(g/\omega_c\), because larger values of \(g/\omega_c\) imply larger oscillation amplitudes within the relevant range over which we have to average; compare the center and right plots in Fig.17. Therefore, for the experimentally most relevant regime where \((\omega_c/2\pi)\Delta t \ll 1\) and \(g/\omega_c \lesssim 1/16\), the effects of time jitter should be negligible.

**Appendix I: Analytical Expression for Rethermalization-Induced Errors**

In this Appendix we derive an analytical expression for rethermalization-induced errors. In particular we show that this expression is independent of the spin-resonator coupling strength \(g\).

Our analysis starts out from the master equation

\[
\dot{\rho} = -i[H, \rho] + \sum_{j=1,2} D[L_j]\rho, \tag{L1}
\]

where the Hamiltonian \(H = \omega_c a^{\dagger}a + gS \otimes (a + a^{\dagger})\) refers to the ideal (noise-free) dynamics and the jump-operators \(L_1 = \sqrt{\kappa_{1}}a, L_2 = \sqrt{\kappa_{2}}a^{\dagger}\) with \(\kappa_1 = \kappa(\bar{n}_{\text{th}} + 1)\) and \(\kappa_2 = \kappa\bar{n}_{\text{th}}\) describe rethermalization of the resonator mode with a rate \(\kappa = \omega_c/\Gamma\) that is enhanced by the thermal occupation number \(\bar{n}_{\text{th}}\). It is convenient to move to an interaction picture, defined by \(\tilde{\rho}(t) = \exp[iHt]\rho(t)\exp[-iHt]\). In this interaction picture, the system’s dynamics is described by

\[
\dot{\tilde{\rho}} = \sum_{j=1,2} D\left[\tilde{L}_j\right]\tilde{\rho}, \tag{L2}
\]

with time-dependent jump operators \(\tilde{L}_j = \exp[iHt]L_j\exp[-iHt]\). Using the exact relation \(\exp[-iHt] = U\exp[-iw_jt\alpha a^{\dagger}U^{\dagger}U_{sp}(t)]\), with the polaron transformation \(U = \exp[p\tilde{S}(a - a^{\dagger})]\) and the pure spin (entangling) gate \(U_{sp}(t) = \exp[i\mu_{\text{sp}}(a^{\dagger}a + a a^{\dagger})]\), the time-dependent jump operators \(\tilde{L}_j\) take on a simple form

\[
\tilde{L}_1(\tau) = \sqrt{\kappa_{1}}\left[e^{-i\omega_{c}\tau}a + (e^{-i\omega_{c}\tau} - 1)\mu S\right],
\]

\[
\tilde{L}_2(\tau) = \sqrt{\kappa_{2}}\left[e^{i\omega_{c}\tau}a^{\dagger} + (e^{i\omega_{c}\tau} - 1)\mu S\right]. \tag{L3}
\]

The formal solution to Eq.(L2) reads

\[
\tilde{\rho}(t) = \tilde{\rho}(0) + \sum_{j} \int_{0}^{t} d\tau D\left[\tilde{L}_j(\tau)\right]\tilde{\rho}(\tau), \tag{L4}
\]
where in the interaction picture the zeroth-order solution \( \tilde{\rho}_0(t) = \tilde{\rho}(0) = \rho(0) \) stays inert, and accounts for the ideal (noise-free) dynamics only in the lab frame, \( \rho_0(t) = \exp[-iHt] \tilde{\rho}_0(t) \exp[iHt] = \exp[-iHt] \rho(0) \exp[iHt] \).

To obtain the first-order correction \( \tilde{\rho}_1(t) \) within a perturbative framework, we re-insert the zeroth-order solution into the dissipator of Eq.(L4), i.e. effectively we take \( \tilde{\rho}(\tau) \rightarrow \rho(0) \), which yields \( \tilde{\rho}(t) \approx \rho(0) + \tilde{\rho}_1(t) \), with

\[
\tilde{\rho}_1(t) = \sum_j \int_0^t d\tau D \left[ \hat{L}_j(\tau) \right] \rho(0). \tag{L5}
\]

Inserting the expressions given in Eq.(L5) into Eq.(L5) and performing the integration, with
\[
\int_0^t d\tau \left[ 1 - e^{\pm i\omega_c \tau} \right]^2 = 2(t - \frac{\sin(\omega_c \tau)}{\omega_c}) \quad \text{and} \quad \int_0^t d\tau \left( 1 - e^{\pm i\omega_c \tau} \right) = t \pm \frac{e^{\pm i\omega_c \tau}}{\omega_c},
\]

one arrives at

\[
\tilde{\rho}_1(t) = \kappa_1 t D[a] \rho(0) + \kappa_2 t D[a^\dagger] \rho(0) + 2(\kappa_1 + \kappa_2) \mu^2 \left( t - \frac{\sin(\omega_c t)}{\omega_c} \right) D[S] \rho(0)
\]

\[
+ \left[ \kappa_1 \mu \left( t - i e^{-i\omega_c t} \right) \right] \left\{ a \rho(0) S - \frac{1}{2} \{a S, \rho(0)\} \right\} + \text{h.c.}
\]

\[
+ \left[ \kappa_2 \mu \left( t + i e^{-i\omega_c t} \right) \right] \left\{ a^\dagger \rho(0) S - \frac{1}{2} \{a^\dagger S, \rho(0)\} \right\} + \text{h.c.}. \tag{L6}
\]

which, for stroboscopic times \( t_m = 2\pi m / \omega_c \) (with \( m \) integer), simplifies to

\[
\tilde{\rho}_1(t_m) = \kappa_1 t_m D[a] \rho(0) + \kappa_2 t_m D[a^\dagger] \rho(0) + 2(\kappa_1 + \kappa_2) \mu^2 t_m D[S] \rho(0)
\]

\[
+ \left[ \kappa_1 \mu t_m \right] \left\{ a \rho(0) S - \frac{1}{2} \{a S, \rho(0)\} \right\} + \text{h.c.} + \left[ \kappa_2 \mu t_m \right] \left\{ a^\dagger \rho(0) S - \frac{1}{2} \{a^\dagger S, \rho(0)\} \right\} + \text{h.c.}.
\]

Next, we perform a transformation back to the lab frame, with \( \rho(t) = \exp[-iHt] \tilde{\rho}(t) \exp[iHt] \). As discussed in the main text, for stroboscopic times the ideal evolution simplifies to \( \exp[-iH t_m] = \exp[i\mu^2 2\pi m S^2] = \exp(-i\phi_m) \exp[i\pi \mu^2 \sigma_1^2 \sigma_2^2] \). The ideal (noise-free) evolution is given by \( \rho_{id}(t_m) = \exp[-iH t_m] \rho(0) \exp[iH t_m] = \rho_{id}(t_m) \otimes \rho_{id} \), where \( \rho_{id}(t_m) = \rho_{id} \exp[i\pi \mu^2 \sigma_1^2 \sigma_2^2] \). Then, the system’s density matrix at time \( t_m \) is approximately given by

\[
\rho(t_m) = \rho_{id}(t_m) + \kappa_1 t_m D[a] \rho_{id}(t_m)
\]

\[
+ \kappa_2 t_m D[a^\dagger] \rho_{id}(t_m)
\]

\[
+ 2(\kappa_1 + \kappa_2) \mu^2 t_m D[S] \rho_{id}(t_m)
\]

\[
+ \left[ \kappa_1 \mu t_m \right] \left\{ a \rho_{id}(t_m) S - \frac{1}{2} \{a S, \rho_{id}(t_m)\} \right\}
\]

\[
+ \kappa_2 \mu t_m \left\{ a^\dagger \rho_{id}(t_m) S - \frac{1}{2} \{a^\dagger S, \rho_{id}(t_m)\} \right\} + \text{h.c.}.
\]

Note that, in the limit \( \kappa_i \rightarrow 0 \), one retrieves the ideal result \( \rho(t_m) = \rho_{id}(t_m) \). Next, we trace out the resonator mode. Assuming the state of the resonator mode to be diagonal in the occupation number basis (in particular, this holds for a thermal state \( \rho_{th} \)), none of the cross-terms contribute to the partial trace, and for stroboscopic times \( t_m \) the state of the qubits is given by

\[
\rho(t_m) = \rho_{id}(t_m) + 2\kappa(2\bar{n}_th + 1) t_m \mu^2 D[S] \rho_{id}(t_m). \tag{L7}
\]

As expected naively, the error term scales with \( \sim \kappa \bar{n}_th \mu^2 \), but it is further reduced by the factor \( \mu^2 = (g/\omega_c)^2 \). Eq.(L7) holds for stroboscopic times \( t_m = 2\pi m / \omega_c \), with \( m \) integer. If \( m^2 = 1/16 \), the ideal evolution \( \exp[-iH t_m] = \exp(-i\phi_{m^2}) \exp[i\pi \sigma_1^2 \sigma_2^2] \) equals a maximally-entangling gate, which (for an initial pure state like \( |\Psi_0\rangle = |\uparrow \uparrow\rangle \)) yields the desired ideal qubit target state \( |\Psi_{tar}\rangle = \exp[i\pi \sigma_1^2 \sigma_2^2] |\Psi_0\rangle \). Then, in the presence of noise, at the nominally ideal time \( t_{max} = \pi / 8 \mu^2 \omega_c = \pi / 8 \sigma_{eff} \) the qubit’s density matrix reads

\[
\rho(t_{max}) = |\Psi_{tar}\rangle \langle \Psi_{tar} | + \frac{\pi \kappa}{4 \omega_c} (2\bar{n}_th + 1) D[S] |\Psi_{tar}\rangle \langle \Psi_{tar} |. \tag{L8}
\]

Therefore, to first order rethermalization-induced noise leads to dephasing dynamics in the eigenbasis of \( S \) with a single such phase flip. Since neither the desired target state \( |\Psi_{tar}\rangle \) nor the initial state \( |\Psi_0\rangle \) is an eigenstate of \( S \), the system loses fidelity with a probability \( \frac{\pi \kappa}{4 \omega_c} (2\bar{n}_th + 1) \); notably, this expression is independent of the spin-resonator coupling strength \( g \).

For the fidelity with the maximally entangled target
Figure 18: (color online). Fidelity $F$ close to the ideal time $t_{\text{max}}$ for $g/\omega_c = 1/16$. The different curves refer to $Q = 10^5$, $k_B T/\omega_c = 2$, i.e. $\bar{n}_{\text{th}} \approx 1.54$, (blue solid, top curve), $Q = 10^6$, $k_B T/\omega_c = 4$, i.e. $\bar{n}_{\text{th}} \approx 3.52$, (red solid) and $Q = 10^4$, $k_B T/\omega_c = 4$ (red dash-dotted). The error $\xi = 1 - F$ can be estimated well with the formula $\xi_k \approx 4\bar{n}_{\text{th}}/Q$, giving (for example) $F \approx 1 - 4 \times 3.52/10^4 \approx 0.9986$. Other numerical parameters: $\Gamma = 0$ and $\omega_q = 0$.

state, we then obtain

$$F = \langle \Psi_{\text{tar}} | \rho( t_{\text{max}} ) | \Psi_{\text{tar}} \rangle = 1 - \frac{\pi}{2} \frac{\kappa}{\omega_c} (2\bar{n}_{\text{th}} + 1),$$  \hspace{1cm} (L9)

with a thermalization-induced error term given by

$$\xi_k = \frac{\pi}{2} \frac{\kappa}{\omega_c} \bar{n}_{\text{th}} + \frac{\pi}{2} Q^{-1}. \hspace{1cm} (L10)$$

This analytical result is in good agreement with our numerical findings (from which we have deduced $\xi_k \approx \alpha_k (\kappa/\omega_c) \bar{n}_{\text{th}}$, with $\alpha_k \approx 4$), showing (i) a linear scaling with the effective rethermalization rate $\sim \kappa \bar{n}_{\text{th}}$, (ii) with a pre-factor $\alpha_k = \pi$ (close to $\sim 4$) that is independent of the spin-resonator coupling strength $g$ and (iii) a constant offset $\sim Q^{-1}$ which is negligible for realistic quality factors $Q \approx 10^5 - 10^6$. The latter is due to photon/phonon emission with a rate $\sim \kappa = \omega_c/Q$ at $T \to 0$. As illustrated further in Fig.18 with a close-up of the fidelity $F(t)$ around the optimal point $t_{\text{max}}$, the error $\xi_k$ can be estimated well with this simple formula, where all temperature related effects are captured by the simple linear expression in the thermal occupation number $n_{\text{th}}$.

Correlated noise model.—An analog analysis to the one presented above can be performed for a master equation with correlated (rather than uncorrelated) noise. In this case, as shown in Appendix J2, the jump-operators are given by $L_1 = \sqrt{\kappa_1} (a + \mu S)$, $L_2 = \sqrt{\kappa_2} (a^\dagger + \mu S)$, which take on a simple form in the interaction picture, namely

$$L_1 (\tau) = \sqrt{\kappa_1} e^{-i \omega \tau} (a + \mu S), \hspace{1cm} (L11)$$

$$L_2 (\tau) = \sqrt{\kappa_2} e^{i \omega \tau} (a^\dagger + \mu S), \hspace{1cm} (L12)$$

as compared to Eq.(L3) within the uncorrelated noise model discussed above. Then, following the same steps as above, the integration $\int_0^t d\tau |1 - e^{\pm i \omega \tau}|^2 = 2(t - \sin(\omega \tau)/\omega_c)$ is simply replaced by $\int_0^t d\tau = t$; accordingly, in this scenario, the pre-factor of the spin dephasing term $\mathcal{D}(S) \rho(0)$ simplifies to $\sim (\kappa_1 + \kappa_2) \mu^2 t$, which for stroboscopic times $t_m = 2\pi n/\omega_c$ is exactly a factor of two smaller than the corresponding rate in Eq.(L6) for the uncorrelated noise model. In summary, along the lines of our previous analysis, for a correlated noise model Eqs.(L7) and (L10) should be replaced by

$$\hat{\rho} (t_m) = \hat{\rho}_{\text{id}} (t_m) + \kappa (2\bar{n}_{\text{th}} + 1) t_m \mu^2 \mathcal{D}(S) \hat{\rho}_{\text{id}} (t_m), \hspace{1cm} (L13)$$

respectively, showing that for uncorrelated spin-resonator noise the rethermalization-induced error is approximately twice as large as for correlated spin-resonator noise; also compare the numerical results presented in Tab. 1.

Appendix M: Analytical Model for Dephasing-Induced Errors

In this Appendix we provide an analytical model for dephasing-induced errors. Neglecting rethermalization-induced errors for the moment, here we consider the following master equation

$$\dot{\rho} = -i [H_{\text{id}}, \rho] + \gamma_0 [\mathcal{D}(\sigma_+^z \rho + \mathcal{D}(\sigma_-^z) \rho], \hspace{1cm} (M1)$$

where $H_{\text{id}} = \omega_c a^\dagger a + g (\sigma_+^z \sigma_-^z) \otimes (a + a^\dagger)$ describes the ideal (error-free), coherent evolution for longitudinal coupling between the qubits and the resonator mode, and $\gamma_0$ is the pure dephasing rate. Since the superoperators $L_0$ and $L_1$ as defined in Eq.(M1) commute, that is $[L_0, L_1] = 0$ (since $[H_{\text{id}}, \mathcal{D}(\sigma_-^z)]X = \mathcal{D}(\sigma_-^z)[H_{\text{id}}, X]$ for any operator $X$), the full evolution simplifies to

$$\rho(t) = e^{L_0 t} \rho(0) = e^{L_1 t} \rho_{\text{id}} (t), \hspace{1cm} (M2)$$

where we have defined the ideal target state at time $t$ as $\rho_{\text{id}} (t) = \exp [L_0 t] \rho(0)$, which, starting from the initial state $\rho(0)$, exclusively accounts for the ideal (error-free), coherent evolution. For small infidelities ($\gamma_0 t \ll 1$), the deviation from the ideal dynamics $\Delta \rho = \rho - \rho_{\text{id}}$ is approximately given by

$$\Delta \rho (t) \approx \gamma_0 t \sum_i \mathcal{D}(\sigma_i^z) \rho_{\text{id}} (t), \hspace{1cm} (M3)$$

showing that (in the regime of interest where $\gamma_0 t \ll 1$) the dominant dephasing induced errors are linearly proportional to $\gamma_0 t \sim \gamma_0/\tau_{\text{eff}} = \gamma_0/\mu^2 \omega_c$, as expected.
here, \( t_q \sim g_{\text{eff}} \) is the relevant gate time which has to be short compared to \( \gamma_\phi^{-1} \).

In what follows, for completeness we derive the same result within a quantum jump approach. Eq.(M1) can be rewritten as

\[
\dot{\rho} = -i[H, \rho] + \mathcal{J} \rho, \tag{M4}
\]

where \( H = H_{\text{id}} - i\gamma_\phi \rho \) and \( \mathcal{J} \rho = \gamma_\phi \sum_i \sigma_i^x \rho_\text{id} \sigma_i^x \). The formal solution to Eq.(M4) reads

\[
\rho(t) = e^{-iHt} \rho(0) e^{iHt} + \int_0^t d \tau e^{-iH(t-\tau)} \mathcal{J} \rho(\tau) e^{iH(\tau-t)}. \tag{M5}
\]

Defining the ideal target state at time \( t \) as

\[
\rho_{\text{id}}(t) = e^{-iH_{\text{id}}(t-\tau)} \rho(\tau) e^{iH_{\text{id}}(t-\tau)}, \tag{M6}
\]

the exact solution given in Eq.(M5) can be iterated, giving an illustrative expansion in terms of the jumps \( \mathcal{J} \). It reads

\[
\rho(t) = \mathcal{U}(t) \rho(0) + \int_0^t d \tau_1 \mathcal{U}(t-t_1) \mathcal{J} \rho(t_1) \rho(0) + \int_0^t d \tau_2 \int_0^{\tau_2} d \tau_1 \mathcal{U}(t-t_2) \mathcal{J} \rho(t_2-t_1) \mathcal{J} \rho(t_1) \rho(0) + \ldots
\]

Here, the \( n \)-th order term comprises \( n \) jumps \( \mathcal{J} \) with free evolution \( \mathcal{U}(t) \rho = e^{-iHt} \rho e^{iHt} \) between the jumps. Up to second order in \( \mathcal{J} \) we then find

\[
\rho(t) = \mathcal{U}(t) \rho(0) + e^{-2\gamma_\phi t} \gamma_\phi \sum_i \sigma_i^x \rho_{\text{id}}(t) \sigma_i^x + \frac{1}{2} e^{-2\gamma_\phi t} \gamma_\phi^2 \sum_{i,j} \sigma_i^x \sigma_j^z \rho_{\text{id}}(t) \sigma_j^z \sigma_i^x + \ldots
\]

For the regime of interest where \( \gamma_\phi t \ll 1 \), we then obtain again the result given in Eq.(M3), where the dominant error term scales linearly with \( \sim \gamma_\phi t \).

**Appendix N: Relaxation-Induced Errors**

In this Appendix we address in detail errors induced by relaxation processes, typically characterized by the timescale \( T_1 \). First, we discuss typical relaxation timescales for different physical platforms, with particular emphasis on their dependence on both temperature \( T \) and qubit-level splitting \( \omega_q \). We conclude that interlevel scattering processes typically play a minor role as compared to pure dephasing induced errors, even in our regime of interest with elevated temperatures of a few Kelvin and small qubit level splittings. Second, for completeness, we numerically verify the expected linear error scaling \( \sim T_1^{-1} \) and—using the fundamental relation \( T_2^{-1} = 1/2T_1 + 1/T_\phi \) [79], with \( T_2^{-1}(T_\phi^{-1}) \) referring to the decoherence (pure-dephasing) rate—give an upper bound on decoherence-induced errors.

1. **Experimental Relaxation Timescales**

Let us first discuss spin qubits in quantum dots where decoherence predominantly results from spin-orbit interaction and hyperfine interaction with nuclear spins [60, 80]. Thereafter we discuss yet another candidate system for the implementation of the proposed hot gate, consisting of nitrogen-vacancy centers coupled to the vibrational mode of a diamond mechanical nano-resonator via strain [52, 92, 93].

(i) Single-electron spin qubits.—For single-electron spins in GaAs quantum dots the inter qubit level spin scattering is typically dominated by spin-orbit interaction in combination with the emission of single piezoelectric phonons, while other relaxation processes are usually negligible [60, 80]. At low temperatures, the corresponding phonon-mediated spin relaxation rate \( \gamma_1 \) shows a well-known, pronounced dependence on magnetic field \( B \), namely

\[
\gamma_1 = T_1^{-1} = A (g_s \mu_B B)^5 / \omega_0^4, \tag{N1}
\]

where \( A \) is a material-specific constant reflecting the effectiveness of the spin-phonon coupling strength, \( \omega_q = g_s \mu_B B \) is the Zeeman splitting (with the \( g \)-factor \( g_s \) and Bohr magneton \( \mu_B \)) and \( \omega_0 \) refers to the quantum dot single-particle level spacing; compare Refs.[60, 80] and references therein. As usual, for elevated temperatures \( k_B T \geq \omega_q \) this relaxation rate is enhanced by a (bosonic) thermal occupation factor \( \bar{n}_\text{th}(\omega_q) \approx k_B T / \omega_q \) (describing stimulated emission of phonons), yielding a linear scaling with temperature, that is an effective relaxation rate \( \gamma_1 \sim \omega_q^4 \times k_B T \) for temperatures much larger than the Zeeman splitting \( (k_B T \gg \omega_q) \) [81].

For very small magnetic fields \( B \), this expression for \( T_1 \) diverges \( (\gamma_1 \to 0) \), because it accounts for single-phonon processes only (with single phonons in resonance with the Zeeman energy \( \omega_q \), as required by energy conservation) and Kramer’s theorem does not allow for spin-orbit-induced spin relaxation in the absence of a magnetic field [60, 80]. When accounting for two-phonon processes, however, \( T_1 \) does converge to a finite value [80]. As shown theoretically in Refs.[83, 84], the corresponding two-phonon spin flip rate becomes the dominating (phonon-mediated) scattering mechanism for sufficiently small magnetic fields \( \lesssim 0.4T \), with a corresponding two-phonon mediated scattering rate of \( \sim 1\text{kHz} \) \( (T_1 \sim 1\text{ms}) \) for \( T \approx 4\text{K} \) in GaAs, reaching very long relaxation times of \( T_1 \approx 1\text{s} \) for \( T \approx 1\text{K} \) and sufficiently small magnetic fields of \( B \lesssim 0.1\text{T} \). Similarly, experiments on the relaxation rate from the two-electron triplet to singlet states as a function of the singlet-triplet energy splitting \( \Delta E_{\text{ST}} \) (referred to as \( \omega_q \) in our analysis) show relaxation times well below 1ms as \( \Delta E_{\text{ST}} \) approaches zero [85], due to
a vanishing phonon density of states; compare Fig.21 in Ref.[60]. Finally, near zero magnetic field \( (\omega_q = 0) \), in GaAs energy relaxation is known to be dominated by direct hyperfine-mediated electron-nuclear flip-flops [60]. For a (relatively small) magnetic field \( B \gg B_n \approx 3\text{mT} \) (with \( B_n \) denoting the effective nuclear magnetic field caused by ambient nuclear spins), however, this mechanism is suppressed efficiently by the mismatch between nuclear and electron Zeeman energies [82], effectively leaving the hyperfine interaction as the well-known, dominating pure-dephasing mechanism for the electron spin qubit [60]. Therefore, as soon as the qubit level splitting \( \omega_q = g_s \mu_B B \) exceeds the typical hyperfine energy-scale in GaAs \( g_{\text{hh}}/2\pi \approx 25\text{MHz} \), one reaches a regime, where \( T_1 \) processes can be neglected compared to pure-dephasing \( \sim T_2^* \) (even at temperatures of a few Kelvin), while easily satisfying the inequality \( g_{\text{hh}} \ll \omega_q \ll \omega_c \) for typical resonator frequencies \( \omega_c/2\pi \sim \text{GHz} \), as required for the implementation of the proposed hot gate. The prospects for a faithful implementation of the proposed hot gate are potentially even more promising when switching to materials such as Si and Ge where both hyperfine interactions with the ambient nuclei (since these materials can be grown nuclear-spin free) and piezoelectric electron-phonon coupling (due to bulk inversion symmetry) are absent [79, 80]; note that the latter typically dominates spin relaxation in GaAs-based systems [60, 83, 84]. In fact, silicon-based experiments have demonstrated \( T_1 \sim 3\text{s} \) at \( B = 1.85\text{T} \) and \( T = 0.15\text{K} \) [86], suggesting (according to the usual thermal enhancement) \( T_1 \sim 0.3\text{s} \) for \( T \approx 1\text{K} \), which is still much longer than the spin-dephasing timescale \( T_2^* \sim 100\mu\text{s} \) quoted in the main text and agrees with the common wisdom that spin lifetimes are orders of magnitude longer than the ones reported for GaAs [79, 87]; compare our subsequent discussion on singlet-triplet qubits.

(ii) Singlet-triplet spin qubits.—For singlet-triplet qubits in silicon relaxation times of \( T_1 \sim 10\text{ms} \) have been demonstrated at zero magnetic field for cryostat temperatures \( T \sim 15\text{mK} \) [87], which exceeds the \( B = 0 \) lifetimes measured in comparable GaAs setups by about two orders of magnitude. As discussed in detail in Appendix D.2, in this system the qubit splitting \( \omega_q \) is set by the well-controlled exchange splitting \( J \), which can be tuned to very small values. For example, in Ref.[87] \( \omega_q/2\pi \approx 16\text{MHz} \), which is much smaller than any relevant resonator frequency \( \omega_c \). As argued in Ref.[87], the measured lifetimes of \( T_1 \sim 10\text{ms} \) (at \( B = 0 \)) are limited by the (small) hyperfine interaction in natural (i.e., not purified) silicon with \( g_{\text{hh}} \sim 3\text{meV} \). Since the effective relaxation rate at elevated temperatures is determined by integrated auto-correlation functions of the bath operators (yielding for example the thermal enhancement factor \( \bar{n}_{\text{hh}}(\omega_q) \approx k_B T/\omega_q \) when coupling to a bosonic bath, as discussed above), very long lifetimes of \( T_1 \sim 10\text{ms} \) (at \( B = 0 \)) can still be expected, even at higher temperatures \( T \sim K \), because the autocorrelation functions of the relevant nuclear spin bath operators do not show a bosonic thermal enhancement factor; conversely, due to their extremely small magnetic moment, nuclear spins can be treated as an infinite temperature bath, even at ultralow temperatures \( \sim 100\text{mK} \) and strong magnetic fields [85]. Therefore, singlet-triplet qubits in silicon should be well suited for the implementation of the proposed hot gate, with tunable qubits splittings much smaller than relevant resonator frequencies \( \omega_q \ll \omega_c \) and relaxation times \( T_1 \) much longer than \( T_2^* \), even at elevated temperatures of a few Kelvin.

(iii) NV-centers.—Since for nitrogen-vacancy (NV) centers in diamond the spin \( T_1 \) time can be several seconds or longer [89–91], even at temperatures of a few Kelvin, it is common practice to neglect the spin decay; compare for example Ref.[52], which may serve as a potential platform for a proof-of-principle implementation of the proposed hot gate. The electronic ground state of the negatively charged NV center is a spin \( S = 1 \) triplet with spin states \( |m_s = 0, \pm 1\rangle \), where the levels \( |\pm 1\rangle \) are split off from \( |0\rangle \) by the zero-field splitting \( D/2\pi = 2.88\text{GHz} \). In the absence of an external magnetic field the states \( |\pm 1\rangle \) are degenerate. As discussed in detail in Refs.[52, 92, 93], such an electronic spin can be coupled to the motion of a mechanical resonator through lattice strain, with perpendicular strain mixing the \( |\pm 1\rangle \) states, which is otherwise a dipole-forbidden transition \( (\Delta m_s = 2) \) [52, 92, 93]. If the system is prepared in the \( |\pm 1\rangle \) subspace, the state \( |0\rangle \) remains unpopulated and the effect of parallel strain plays no role [52], yielding an effective qubit with qubit splitting \( \omega_q = 2\gamma_{\text{NV}} B \) (with \( \gamma_{\text{NV}}/2\pi = 2.8\text{MHz}/\text{G} \)), that is coupled to the mechanical resonator mode of frequency \( \omega_c \gg \omega_q \). Then, in the absence of an external magnetic field \( (\omega_q = 0) \), the effective Hamiltonian \( H_{\text{eff}} \) for this spin-resonator system takes on the desired form, that is \( H_{\text{eff}} = \omega_c a^\dag a - g_s \sigma^z \otimes (a + a^\dag) \), where \( \sigma^z = |+1\rangle\langle -1| + \text{h.c.} \) and \( g_s \) is the transverse single-phonon strain-coupling strength [92]. At first sight, in this setup the spin-resonator coupling \( g_s \) is static and not easily tunable; hence, while it does not provide an universal two-qubit primitive, it can nevertheless be used to generate entanglement at elevated temperatures. The spin-resonator coupling may, however, effectively be switched on and off by making use of the hyperfine coupling to adjacent single nuclear spins where quantum information can be stored with qubit memory lifetimes exceeding one second [94].

2. Error Scaling

To quantitatively capture the effect of relaxation-induced errors, we have analyzed the master equation

\[
\dot{\rho} = -i[H, \rho] + \gamma_1 \sum_i D[\sigma_i^+] \rho, \tag{26}
\]

where the first term refers to the ideal, coherent dynamics and the second term describes single-spin relaxation with a rate \( \gamma_1 = T_1^{-1} \); incoherent excitation processes could
be included as well, with additional terms of the same form with the appropriate replacement $\sigma_i^+ \to \sigma_i^-$, but are omitted here for clarity. Along the lines of our analysis for dephasing-induced errors, the relaxation-induced error is expected to scale linearly with the relaxation rate as $\xi_\gamma \sim \gamma_1 / g_{\text{eff}}$, that is

$$
\xi_\gamma \approx \alpha_\gamma \frac{\gamma_1}{\omega_c},
$$

with the pre-factor $\alpha_\gamma = c_\gamma / \mu^2$, where $\mu = g / \omega_c$. As shown in Fig. 19, based on numerical simulations of Eq. (N2), this linear error scaling has been verified numerically, yielding the numerical pre-factor $c_\gamma \approx 0.38$, that is $\alpha_\gamma \approx 0.38 / \mu^2$. This numerical pre-factor coincides very well with the value obtained for the dephasing-induced error $\sim \Gamma$ (when properly accounting for the factor of four in our definition $\Gamma = 2/T_2^*$; compare the corresponding master equation Eq. (7) in the main text); recall $\xi_\Gamma \approx 4 \alpha_\Gamma \gamma_1 / \omega_c$, with $4 \alpha_\Gamma \approx 0.4 / \mu^2$ and $\gamma_1 \gamma_\phi \Gamma / \omega_c$ (to match with our definition of $\alpha_\gamma$). Accordingly, in the typical scenario where $T_2^* \ll T_1$ (as discussed in the previous subsection), indeed relaxation-induced errors (as well as similar incoherent excitation processes) can be safely neglected. In the opposite regime, where pure-dephasing processes are negligible (such that the decoherence timescale reaches its fundamental upper limit $T_2 \leq 2 T_1$, i.e. the qubit coherence is limited by spin flips), the total error $\xi_{\text{dec}}$ induced by qubit decoherence is simply given by $\xi_{\text{dec}} \approx \xi_\gamma \approx \alpha_\gamma \gamma_1 / \omega_c$. Finally, in the worst-case regime where the pure-dephasing rate and the relaxation rate are comparable ($\gamma_\phi \approx \gamma_1$), the total error due to qubit decoherence amounts to $\xi_{\text{dec}} = \xi_\gamma + \xi_\Gamma \approx 2 \alpha_\gamma \gamma_1 / \omega_c \approx 2 \alpha_\gamma \Gamma / \omega_c$, i.e. just a factor of two larger than the decoherence-induced error considered in the main text.

Figure 19: (color online). Relaxation-induced error $\xi_\gamma$ for $g / \omega_c = 1 / 8$ (blue circles), $g / \omega_c = 1 / (8 \sqrt{2})$ (black squares) and $g / \omega_c = 1 / 16$ (red diamonds). Other numerical parameters: $k_B T / \omega_c = 0.01$, $\kappa = 0$, $\Gamma = 0$ and $\omega_q = 0$.

Figure 20: (color online). Total average gate error $\bar{E}$ (in percent) as a function of both the effective rethermalization rate $\sim \kappa / \omega_c \bar{n}_{\text{th}} \sim \bar{n}_{\text{th}} / Q$ and the spin dephasing rate $\sim \Gamma / \omega_c$ for $g / \omega_c = 1 / 4$ (top) and $g / \omega_c = 1 / 8$ (bottom). Other numerical parameters: $k_B T / \omega_c = 2$ and $\omega_q = 0$.

### Appendix O: Average Gate Fidelity

The average gate fidelity $\bar{F}$ is a useful measure in order to quantify how well the completely-positive, trace-preserving quantum operation $\mathcal{M}$ (in the presence of noise) approximates a given unitary gate $U_{\text{id}}$, which represents the ideal (noise-free) evolution. Formally, it is defined as

$$
\bar{F} = \int d\psi \langle \psi | U_{\text{id}}^{\dagger} \mathcal{M} (| \psi \rangle \langle \psi |) U_{\text{id}} | \psi \rangle,
$$

where the integral runs over the uniform (Haar) measure $d\psi$ on state space, with $\int d\psi = 1$ [95]. As shown in Ref.[95], $\bar{F}$ may be re-expressed as

$$
\bar{F} = \frac{d F_{\text{ent}} + 1}{d + 1},
$$

where $d$ is the dimension of the Hilbert space ($d = 4$ for two qubits) and the entanglement fidelity $F_{\text{ent}}$ is the
fidelity of the state obtained when \( M \) acts on one half of a maximally entangled state with the state obtained from the action of the ideal evolution; it is given by

\[
F_{\text{ent}} = \frac{1}{d^3} \sum_{P \in G} \text{tr} \left[ P U_{\text{id}}^\dagger M (P) U_{\text{id}} \right]. \tag{O3}
\]

Here, \( G \) is a set of \( d \times d \) unitary operators, forming a basis for a qudit, i.e., \( \sum_{j,k=1 \ldots d^2} \delta_{jk} P_j \). For two qubits we may take the set of Pauli matrices modulo phase, comprising in total 16 operators \( G = \{ I, \sigma^x, \sigma^y, \sigma^z \} \), where \( i = 1, 2, \alpha = x, y, z \). Experimentally, \( F \) may be determined using standard state tomography [95].

Errors.—The average gate error (fidelity) is defined as \( E = 1 - F \). As follows directly from Eq.(O2), it is related to the entanglement fidelity \( E_{\text{ent}} = 1 - F_{\text{ent}} \) via \( E = d/(d+1) \times E_{\text{ent}} \); thus, for two qubits \( E = (4/5) E_{\text{ent}} \).

Numerical results.—Numerical results for the average gate error \( \bar{E} \) are presented in Fig.20. Here, the map \( M(P) \) is given implicitly as \( M(P) = \text{tr}_a [ e^{\mathcal{L}_{\text{th}} P} \rho_{\text{th}} ] \), where the superoperator \( \mathcal{L} \) is the Liouvillian associated with the master equation given in Eq.(7) in the main text, which includes undesired processes due to rethermalization of the cavity mode and dephasing of the spins. Broadly speaking, our numerical results for the (average) gate error \( E \) are comparable to the ones obtained for the state fidelity \( \xi = 1 - F \), as discussed in the main text. First, comparison of our results for \( g/\omega_c = 1/4 \) and \( g/\omega_c = 1/8 \) shows that rethermalization-induced errors are approximately independent of the spin-resonator coupling \( g \); for example, for \( \Gamma = 0 \) and \( \kappa/\omega_c \tilde{n}_r = 2.5 \times 10^{-3} \) we find \( E_r \approx 0.82\% \) for both \( g/\omega_c = 1/4 \) and \( g/\omega_c = 1/8 \), respectively. Second, as expected, the dephasing induced error scales as \( E_F \sim g^2/\mu \); for example, as shown in Fig.20, for \( \kappa = 0 \) and \( \Gamma/\omega_r = 1.5 \times 10^{-3} \), we find \( E_F \approx 0.376\% \) and \( E_F \approx 1.49\% \approx 4 \times 0.376\% \) for \( g/\omega_c = 1/4 \) and \( g/\omega_c = 1/8 \), respectively.
