**ABSTRACT:** Reproducible and in situ microbial detection, particularly of microbes significant in urinary tract infections (UTIs) such as *Candida albicans*, provides a unique opportunity to bring equity in the healthcare outcomes of disenfranchised groups like women in low-resource settings. Here, we demonstrate a system to potentially detect vulvovaginal candidiasis by leveraging the properties of multifilament cotton threads in the form of microfluidic-thread-based analytical devices (μTADs) to develop a frugal microbial identification assay. A facile mercerization method using heptane wash to boost reagent absorption and penetration is also performed and is shown to be robust compared to other existing conventional mercerization methods. Furthermore, the twisted mercerized fibers are drop-cast with media consisting of L-proline β-naphthylamide, which undergoes hydrolysis by the enzyme L-proline aminopeptidase secreted by *C. albicans*, hence signaling the presence of the pathogen via simple color change with a limit of detection of $0.58 \times 10^6$ cfu/mL. The flexible and easily disposable thread-based detection device when integrated with menstrual hygiene products showed a detection time of 10 min using spiked vaginal discharge. The developed method boasts a long shelf life and high stability, making it a discreet detection device for testing, which provides new vistas for self-testing multiple diseases that are considered taboo in certain societies.

**INTRODUCTION**

Presenting as the most common outpatient disease, the incidence of urinary tract infections (UTIs) is reported at least once in 50–60% of adult women worldwide.\(^1\) The regular occurrence and recurrent nature of certain UTIs manifest themselves as increased burdens on primary healthcare systems, as their incidence as a complication has been linked to multiple additional diseases such as diabetes and postpregnancy infections.\(^1\)–\(^6\) Along with a significant economic burden,\(^7\) UTIs have a prominent global social burden as well, leading to a significant drop in the quality of life in the form of sexual, physical, and emotional deterioration particularly in the lives of women.\(^2\)–\(^9\) The development of UTIs exacerbates the existing inequalities present in societal structures particularly affecting economically and socially disenfranchised women, which tend to have lower access to healthcare facilities.\(^2\)–\(^9\)–\(^11\)

The disparity is further cemented by the lack of resources present for the reliable diagnosis of UTIs like bacterial vaginosis (BV) and vulvovaginal candidiasis (VVC), denying high-risk groups information vital for informed decision making.\(^5\),\(^6\) Particularly in the case of VVC, the gold standard of diagnosis consists of a combined approach integrating microscopic examination from a vaginal or vulval swab with relevant symptoms presenting on the patient.\(^5\),\(^6\)

Around 75% of women belonging to childbearing age experience VVC once in their life. Up to 9% of women in different populations experience >3 episodes per year, considered as recurrent vulvovaginal candidiasis (RVVC).\(^12\) Denning et al. estimated that by 2030, the population of women with RVCC each year will increase to almost 158 million. This alone leads to the economic burden from lost productivity of up to US$14-39 billion annually.\(^4\) These facilities are limited to testing labs frequently absent or overburdened in low-resource areas and do not facilitate reliable in situ self-diagnosis of the infection, making cost a limiting factor in the diagnosis of UTIs in high-risk low-income groups. This inequality is most pronounced in developing areas where the lack of substantial public outreach and existing societal taboos results in instances of shame and guilt associated with contracting UTIs, lowering the overall number of cases reported and tracked.\(^13\),\(^14\) The lack of reliable, rapid, and inexpensive tools to self-diagnose a UTI in a discreet...
manner presents a sizable problem affecting a large section of vulnerable people leading to underdiagnosis of the problem and a severe gap of information due to the inability to test a large representative part of the population.

The loss of equity due to the erosion of autonomy disallows personal choice in health significant decisions that furthers the burden of the disease and loss of productivity, undermining the social upliftment of many disenfranchised people. Sustainable and more equitable growth on the lines of the sustainable development goals put forth by the United Nations, particularly goal 3 and goal 5, calls for the promotion of development goals put forth by the United Nations, and more equitable growth on the lines of the sustainable properties such as low-volume operation, greater fluidic devices. Microfluidics possesses multiple favorable approaches to fabrication, which can further be automated.26−32 Paper-based analytical devices or μPADs have seen applications in fields such as diagnostics,29,33,34 environmental monitoring,27 manufacturing, and food safety control.35

A further simplified version of analytical devices leverages threads as the base medium has garnered significant attention recently.36−45 These thread-based analytical devices or μTADs provide further advantages of not needing the creation of barriers and wells on the substrate itself. μTAD manufacturing does not need multiple complicated steps and is usually done via household items such as sewing needles or machines. These devices also easily integrate into objects such as sensors and can provide additional tensile strength to the added object.37 The base processes of operation in the μTAD are driven by capillary action between the threads that drive the sample to the sites where reagents are immobilized so as to promote a reaction.38 These reagents can be designed to leverage detection techniques such as colorimetry,47−49 which provides a qualitative signal to the eye or to a smartphone-based detection, which are further highlighted by the thread’s white color.49−51 Owing to their utility, μTADs have been used to perform a myriad of assays including glucose assays,52 enzyme-linked immune-sorbent assays (ELISA),53 immuno-chromatographic assays,54−61

Using the tenants of frugal science that promote the development of cost-effective and highly scalable solutions,62 we have combined multifilament threads with a simple colorimetric test, which uses an enzyme−substrate reaction as a means of detecting the target biomarker. Generally, the wicking property is essential in thread devices and is generally impeded by the presence of hydrophobic substances like wax and binders added to cotton threads in the manufacturing process.30,63 This issue has been combatted by mercerizing the thread to improve tensile and absorbing properties.64 Owing to their utility, μTADs have been used to perform a myriad of assays including glucose assays,52 enzyme-linked immune-sorbent assays (ELISA),53 immuno-chromatographic assays,54−61

affect the pH of the substrate, thereby hindering the outcome of the colorimetric test. To answer this burgeoning problem, our group chose to explore and develop a noncaustic and easy-to-use mercerization option using heptane wash in our experiments. Then, we leveraged the mercerized μTADs as a tool for microbial assay, which employs a colorimetric substrate specific to a secretory enzyme of *Candida albicans*. The relevant colorimetric substrate was drop-cast onto the thread device, which wicked it up and created a device, which could signal the presence of microbe qualitatively with a clear and distinct color change. We have also integrated μTADs into menstrual hygiene products, allowing for the detection of *C. albicans* in simulated vaginal discharge samples, signaling an infection (Figure 1). To the best of our knowledge, this is the first study involving μTADs and menstrual hygiene products like napkins and tampons for in situ detection of vulvovaginal candidiasis in a robust and discreet manner, which can be deployable in resource-constrained settings.

### RESULTS AND DISCUSSION

**Characterization of Mercerization Methods.** Commercial mercerization methods tend to use harsh chemicals with high pH, which if left as a residue can be hard to remove and may influence the results of colorimetric, immuno, and pH-based assays performed on it. To test the effect of the mercerization method on a pH assay, we used a thread substrate to perform a pH-based colorimetric test in which phenol red dye was drop-cast on the thread matrix. Then, the color change of the dye was noted to assess the pH of the thread. We observed that the in-lab developed heptane wash technique, compared to other mercerization methods (Figure 2), was not caustic and easy to clean, therefore not impeding the color change in the thread by possible residues. The developed method allows for the addition of a new method to the arsenal of mercerization methods, potentially increasing sensitivity in assays in which pH is the principle indicating property being pursued. The thread’s wicking properties are the most essential part of a μTAD, and since the mercerization methods are applied to boost the same, it is essential to compare different methods available in their mercerizing merit. We performed experiments to ascertain the water absorbency and water penetration rates of two commercially available threads that were used as the matrix for developing μTADs. The threads used were twisted multifilament cotton (TMC) thread and piping white glazed cotton (PWGC) thread. These two particular threads are representative of the majority of threads found in the market. The mercerization methods tested include a sodium carbonate (Na₂CO₃) treatment, a sodium chloride (NaCl)–hydrogen peroxide (H₂O₂)–hydrochloric acid (HCl) treatment, and our lab’s proposed heptane treatment.

We assessed the penetration rate of water through 10 cm of thread after adding 150 μL of the sample to both the threads and the distance the water wicked to was noted with respect to time and plotted for all of the methods and untreated thread (Figure 3). We found that mercerized threads possessed significantly more rapid penetration rates, possibly due to the removal of hydrophobic substances and binders. On the other hand, untreated threads displayed poor or nil penetration of dye due to the presence of hydrophobic and waxy residues. In between the mercerization methods, varying results were found for both threads. In the TMC thread (Figure 3a), heptane wash performed better than the NaCl–H₂O₂–HCl treated thread, but the best results were given by Na₂CO₃ treatment. In the PWGC thread (Figure 3b), the heptane wash had comparable results to the Na₂CO₃ treatment, but the NaCl treatment afforded the best results. In both results, the heptane

**Figure 3.** Water penetration rate (comparison) of (a) TMC thread and (b) piping thread.
wash performed best as a general method of mercerization with reliably robust results in both threads. A water absorbency assay was also performed on the TMC and PWGC threads in which the water absorbency was found out of 100% for all of the methods and plotted (Figure 4). The heptane wash performed best in the TMC thread (Figure 4a) and was comparably effective to the other methods in the PWGC thread (Figure 4b), where the Na₂CO₃ showed the best performance. We found that heptane wash was the best general-purpose mercerization method compared to other commercial methods. A typical stress–strain curve is shown in Figure 5. We observed that treatment of TMC and PWGC with heptane, NaCl-H₂O+HCl, and Na₂CO₃ has a considerable effect on the tensile strength. TMC thread showed maximum tensile stress around 53.25 MPa, which is significantly higher than their treated counterparts, which has a breaking point around 29 MPa. However, in the case of PWGC thread, both untreated and heptane-treated threads showed similar tensile stress values. On the other hand, NaCl- and Na₂CO₃-treated threads showed slightly lesser tensile stress.

Thread-Based Colorimetric Microbial Assay. As a way to test the efficacy of the medium, we used thread as the matrix for a detection assay for *C. albicans*, a major opportunistic fungal pathogen causing invasive and debilitating female genital diseases.²³⁶,⁸ The gold standard methods for diagnosing *C. albicans* infections include culture and nucleic acid-based testing, which are labor- and technically intensive. Instead, we implemented a method using L-proline β-naphthylamide (PRO) substrate for targeting the enzyme L-proline aminopeptidase, secreted by *C. albicans* to indicate its presence in solution within 10 min colorimetrically with a pink hue using cinnamaldehyde as an indicator. The assay demonstrated competence quantitatively, indicating the presence of *C. albicans*, as we observed that the intensity of the pink color increased as the concentration of *C. albicans* was increased (Figure 6).

Leveraging the quantitative change of color is a way to visually signal the presence of *C. albicans*. We developed a frugal and robust μTAD and assessed implementing the thread as an alternative substrate to the culture-based time-intensive methods used in diagnostic labs. We also assessed the effect of

![Figure 4. Water absorbency assay (comparison) of (a) TMC thread and (b) piping thread. Each experiment was performed three times. Average value ± standard deviation was measured.](image)

![Figure 5. Stress–strain curve for different mercerization methods: (a) piping thread and (b) TMC thread.](image)

![Figure 6. Thread-based colorimetric assay using heptane-mercerized (a) TMC thread and (b) piping thread.](image)
mercerization on the intensity of the color change by plotting the G-channel intensities of all of the color changes in the treated and untreated thread with respect to the concentration of *C. albicans* present (Figure 7), particularly by heptane wash.

Figure 7. G-channel intensity comparison of mercerization methods in (a) TMC thread and (b) piping thread. Each experiment was performed three times. Average value ± standard deviation was measured.

Figure 8. *C. albicans* detection in spiked vaginal discharge using thread-device embedded in sanitary napkins: (a) TMC thread and (b) piping thread.
Compared to the untreated thread, heptane-treated thread showed better results for lower concentrations of C. albicans and comparable results for higher concentrations, a phenomenon more pronounced in the PWGC thread (Figure 7b) than the TMC thread (Figure 7a). Compared to other methods of mercerization, heptane wash showed comparably robust results to the Na₂CO₃-treated thread. In the PWGC thread, we observed relatively better performance of heptane wash compared to the other mercerization methods and to the mercerization in the TMC thread. These results further prove the utility of heptane wash as a viable mercerization alternative to traditional methods.

Vulvovaginal Candidiasis Detection Device. The true utility of the μTAD developed is explored as a wearable, robust, and in situ detection device for vaginal infections. The flexible and discreet nature of the device allows for its seamless integration into menstrual hygiene products, particularly sanitary napkins and tampons (Figures 8 and 9). When the μTAD was combined with menstrual hygiene products, the signaling ability was tested using simulated vaginal discharge samples. The results showed robust signaling and color change, which could be used to detect infection. Biochemical indication of infection tends to be a long and arduous process involving diagnostic labs and culture times of up to 24–72 h requiring significant prior expertise to perform. The high volumes of biohazardous waste produced can pose great disposal and storage issues as well. As a result, low-resource settings tend to lack access to robust testing facilities. Our proposed method is frugal, robust, and simple enough to be performed at home discreetly with little to no technical expertise. When integrated with menstrual hygiene products, the device does not need additional disposal methods and can be disposed of safely, mainly through incineration, like other menstrual hygiene products. These devices have been shown to have a significant shelf life and can be used immediately, circumventing the need for fresh reagent preparation.

Realistically, the number of pathogens that lead to the development of UTIs span a wider range. Compared to the number of infections caused by Candida species, Enterobacteriaceae cause the majority of UTIs detected.69,70 As a means to widen the net cast by the device when testing for UTIs, multiplexing multiple detection modalities such as nitrite and leukocyte esterase activity tests onto a singular thread-device embedded in tampons: (a) TMC thread and (b) piping thread.

![Figure 9. C. albicans detection in spiked vaginal discharge using thread-device embedded in tampons: (a) TMC thread and (b) piping thread.](image)

CONCLUSIONS

Our research evidently establishes the utility of thread as a viable substrate for microbial detection assays showing multiple desirable properties such as low cost and ease of disposal. We developed a completely novel device for the detection of a globally significant disease, vulvovaginal candidiasis, which relies on enzyme (L-proline aminopeptidase) and substrate (L-proline β-naphthylamide) reaction to the presence of pathogen or microbe. Furthermore, our research proposes a new and viable mercerization method of using heptane wash (≥0.21 US$) to boost absorption and penetration rates in threads and shows how this method is highly robust compared to other methods of mercerization. The efficacy of the method demonstrated provides another option for mercerizing threads, which can benefit from the advantageous properties of heptane, mainly its nonpolar and noncaustic nature, availability, and ease of separation. We also achieved a low cost of 0.22–0.28 US$ for the thread-integrated sanitary napkin or tampon test for C. albicans. Additionally, the ease of manufacture and high scalability of its production due to easily automated production and less added parts make it perfect for use in resource-scarce settings. This approach also paves the way for other wearable devices used to detect diseases that disenfranchise women, especially those that are sexually transmitted. We envisage to improve and further explore better manufacturing methods aimed toward reducing evaporation-linked degradation and integrating image processing techniques through smartphones to boost detection time and objectivity in results.

EXPERIMENTAL SECTION

Materials. Twisted multifilament cotton (TMC) thread (Simco) and piping white glazed cotton (PWGC) thread (Simco) were purchased from a local craft store. Sodium chloride (NaCl), hydrogen peroxide (H₂O₂), sodium carbonate (Na₂CO₃), acetic acid, glycerol, urea, and glucose were procured from Merck, India. Hydrochloric acid (HCl), n-heptane, and potassium hydroxide were obtained from Loba Chemie and SRL, India. L-proline β-naphthylamide (PRO) and p-dimethylaminocinnamaldehyde (DCA) were purchased from Sigma-Aldrich, India, and Loba Chemie, India. Calcium hydroxide, bovine serum albumin (BSA), and lactic acid were procured from Titan Biotech, HiMedia, and Finar Limited, India. Sanitary napkins and tampons (Bella) were procured from a local pharmacy. C. albicans (ATCC 24433) was taken from the culture collection at Mycology Laboratory, Department of Microbiology, Kasturba Medical College, Manipal.

Thread Mercerization. Method 1: NaCl, H₂O₂, and HCl-Based Method. Twisted multifilament cotton (TMC) and piping white glazed cotton (PWGC) thread pieces (3 cm) were taken and boiled in 2 M NaCl solution at 100 °C for 30 min on a heating mantle. Then, the thread pieces were transferred to 0.01% H₂O₂ and soaked for 5 min, followed by soaking in 0.01 M HCl for 5 min. Further, the thread pieces were soaked and washed in Milli-Q water three times for 10 min each and then dried in a hot-air oven at 100 °C for 1.5 h.
Method 2: Na₂CO₃-Based Method. TMC and PWGC thread pieces (3 cm) were boiled in 10 mg/mL sodium carbonate (Na₂CO₃) solution at 100 °C for 5 min on a heating mantle, followed by soaking and washing in Milli-Q water three times for 10 min each. The thread pieces were dried in a hot-air oven at 100 °C for 1.5 h.

Method 3: Heptane Wash-Based Method. TMC and PWGC thread pieces (3 cm) were dipped in appropriate volume of n-heptane solvent and washed thoroughly three times (for about 30 s each), replacing the solvent before every wash. The thread pieces were then washed in Milli-Q water three times and dried in a hot-air oven at 100 °C for 1.5 h.

pH Study of Threads Treated with Different Mercerization Techniques. To assess the effect of the mercerization techniques on the pH of the thread, different mercerized TMC and PWGC thread pieces (3 cm) were taken and 100 μL of phenol red pH indicator dye solution was added to it. The change in the color of the indicator on the thread based on the pH of the thread was captured using Canon Eos 3000D DSLR camera, and the pH values of the thread pieces corresponding to the different mercerization treatments were measured using pH strips.

Penetration Rate of Threads. To analyze the water penetration rate in different mercerized TMC and PWGC threads (10 cm), 150 μL of phenol red indicator solution in water was added and the distance moved by the dye in thread with time was noted using a ruler and stopwatch.

Percentage Water Absorbency of Threads. TMC and PWGC thread pieces (3 cm) treated through different mercerization techniques were taken and their dry weight was measured using a weighing balance. Further, they were dipped and soaked for 5 min in 1 mL of water taken in vials separately. The water-soaked thread pieces were then weighed again, and this weight was recorded as the wet weight of the threads. The percentage water absorbency was measured using the formula \[ \frac{\text{(wet weight} - \text{dry weight})}{\text{wet weight}} \times 100 \].

Tensile Testing. The experiment of tensile testing was done in the universal testing machine (Instron 3366). In general, tensile test is used to measure the tensile strength of the specimen by applying load on two ends. In this study, tensile testing was done for the TMC and PWGC threads treated with heptane, NaCl-H₂O₂-HCl, and Na₂CO₃ and untreated thread (control) using universal testing machine. Threads measuring 10 cm were clamped onto the grip mechanism connected to the machine, and the load was provided.

Thread-Based Colorimetric Detection of C. albicans. PRO substrate solution (50 μL, 2 mg/mL) was added to the three sets of mercerized TMC and PWGC threads (3 cm) and dried for 15 min after the substrate solution wicked properly through the threads. Next, 100 μL of C. albicans cell suspensions (different cell concentrations or CFU/mL spiked in water) was added to the thread pieces and incubated at 37 °C for 15 min. DCA indicator solution (80 μL, 5.1 mg/mL) was added, and the color change in the thread device was captured after 10 min using a Canon Eos 3000D DSLR camera. The green channel intensity values of the color formed in the different threads were measured from the images using Fiji software and normalized suitably.

Further, we embedded the PRO substrate-imbibed 3 cm TMC and PWGC thread pieces (heptane wash mercerized) in the inner layer of sanitary napkins and tampons. Simulated vaginal discharge samples (300 μL/thread; 3.510 g/L sodium chloride, 1.4 g/L potassium hydroxide, 0.222 g/L calcium hydroxide, 0.018 g/L bovine serum albumin, 2 g/L lactic acid, 1 g/L acetic acid, 0.160 g/L glycerol, 0.4 g/L urea, 5 g/L glucose, pH 4.6) spiked with C. albicans (2.24 × 10⁶ CFU/mL) were added to the sanitary napkins and tampons and incubated at 37 °C for 15 min. DCA indicator (80 μL/thread) was added to the thread-embedded spots of sanitary napkins and tampons, and the color change in the regions was captured after 10 min using a Canon Eos 3000D DSLR camera.
