Some of the important results from the COSY-Jülich spin programme are summarised. These include the measurement of the deuteron beam momentum through the excitation of a depolarising resonance, which allowed the mass of the $\eta$ meson to be determined to high precision. The charge exchange of polarised deuterons on hydrogen gave rise to a detailed study of the spin dependence of large angle neutron-proton elastic scattering amplitudes. The measurements of the cross section and analysing powers for pion production in both $pp$ and $pn$ collisions at 353 MeV could be described very successfully in terms of a partial wave decomposition.

I. INTRODUCTION

It was once claimed that in strong interaction physics “Spin is an inessential complication” [1]. This rather negative attitude ignores certain practical applications and surely dismisses the beauty inherent in many phenomena involving particle polarisation. Recognising this, a programme was outlined several years ago to exploit the possibilities of carrying out experiments with polarised beams and targets at ANKE [2]. This facility is based around a magnetic spectrometer sited at an internal target station of the COoler SYnchrotron and storage ring COSY of the Forschungszentrum Jülich. The basic features of the complex were described in Ref. [2] and we shall here concentrate on a few of the fruits of the spin programme.

COSY can accelerate and store polarised protons and vector and tensor polarised deuterons up to momenta of 3.7 GeV/c. In addition to unpolarised hydrogen and deuterium cluster-jet targets, ANKE is also equipped with polarised $\bar{H}$ and $\bar{D}$ gas target cells so that spin correlations can be studied as well as beam and target analysing powers.

In the following three sections we first show how, in experiments with polarised deuteron beams at a storage ring, the beam momentum can be determined very precisely through the study of artificially induced depolarising resonances. This led to a determination of the mass of the $\eta$ meson that is as precise as any other in the literature. The nucleon-nucleon programme has two distinct elements, the most developed being the charge exchange of tensor polarised deuterons, which gives immediate access to the tensor amplitudes in large angle neutron-proton scattering. However, in addition, measurements are made in proton-proton elastic scattering with polarised beam and target in angular regions where little reliable data exist. Finally, a variety of spin-dependent data on pion production in nucleon-nucleon collisions near threshold have been taken and analysed. These permitted a full partial-wave analysis to be carried out in the domain where two protons emerge almost bound.

II. BEAM MOMENTUM DETERMINATION AND THE MASS OF THE $\eta$ MESON

A big challenge that one often faces in a precision experiment at a storage ring is the determination of the beam momentum with sufficient accuracy. Although the revolution frequency $f_0$ can be measured with a relative precision of around $10^{-5}$, there are much greater uncertainties in the exact orbit of the particles in the ring. A way of overcoming this problem was proposed many years ago [4] and has since been implemented at several electron colliders. Spin is here very much the essential element.

The spin of a polarised beam particle in a storage ring precesses around the normal to the plane of the machine. A horizontal rf field from a solenoid can induce depolarising resonances such that the beam depolarises when the frequency of the externally applied field coincides with that of the spin precession in the ring. The depolarising resonance frequency $f_r$ depends upon the revolution frequency of the machine and the kinematical factor $\gamma = E/mc^2$, where $E$ and $m$ are, respectively, the particle total energy and mass of the particle. For a planar accelerator where there are no horizontal fields,

$$f_r/f_0 = k + \gamma G,$$

where $G$ is the particle’s gyromagnetic anomaly and $k$ is an integer. The combination of the measurements of the revolution and depolarising frequencies allows the evaluation of $\gamma$ and hence the beam momentum $p$.

The depolarising resonance technique was applied for the first time at COSY with a vector polarised deuteron beam of momenta around 3.1 GeV/c [5]. The deuterons were accelerated with a rf cavity and, once the required momentum was reached, a barrier bucket cavity was used to compensate for the energy losses incurred through the beam-target interactions. The depolarising solenoid had an integrated maximum longitudinal $rf$ magnetic field of $\int B_{rms} \, dt = 0.67$ T mm at a $rf$ voltage of 5.7 kV rms. The value of $k = 1$ in Eq. (1) corresponds to frequencies that were in the middle of the solenoid range of 0.5–
A vector polarised beam leads to an asymmetry in the scattering from a carbon target, which could be measured with the EDDA detector. Since only the frequency of the depolarising resonance needed to be determined, an absolute calibration of this device at different deuteron momenta was not required. Figure 1 displays an example of this relative polarisation as a function of the solenoid frequency for a fixed beam momentum. When the frequency of the solenoid coincides with the spin-precession frequency, the beam is maximally depolarised. The structures, especially the double peak in the centre, are caused by the interaction of the deuteron beam with the barrier bucket cavity. However, these did not affect the mean position, which could be fixed with a precision of \( \approx 10^{-5} \). The full width at half maximum, which was typically in the region of 80-100 Hz, is mainly a reflection of the momentum spread within the beam. If this were the only significant effect, it would correspond to \( (\delta p/p)_{\text{rms}} \approx 2 \times 10^{-4} \).

The structures, especially the double peak in the centre, are caused by the interaction of the deuteron beam with the barrier bucket cavity. However, these did not affect the mean position, which could be fixed with a precision of \( \approx 10^{-5} \). The full width at half maximum, which was typically in the region of 80-100 Hz, is mainly a reflection of the momentum spread within the beam. If this were the only significant effect, it would correspond to \( (\delta p/p)_{\text{rms}} \approx 2 \times 10^{-4} \).

The other frequency required in the evaluation of Eq. (1), i.e., that of the circulation in COSY, was measured by using the Schottky noise of the deuteron beam. The statistical distribution of the charged particles in the beam leads to random current fluctuations that induce a voltage signal at a beam pick-up in the ring. The Fourier transform of this voltage-to-time signal by a spectrum analyser delivers the frequency distribution around the harmonics of the revolution frequency of the beam. As mentioned in Sec. III, this phenomenon is also used at COSY to measure the luminosity in an experiment. All the data acquired at a particular beam momentum are presented in Fig. 2. The small tail seen at low frequencies corresponds to beam particles that escaped the influence of the barrier bucket cavity but still circulated in COSY. The statistical uncertainty in the weighted arithmetic mean was in all cases below 0.2 Hz compared to the typical 1.4 MHz shown in the figure. This means that, under ideal conditions, the left hand side of Eq. (1) could be measured with a precision of better than \( 10^{-5} \).

The great efforts expended in determining precisely the deuteron beam momentum were justified in order to measure the mass of the \( \eta \) meson from the missing-mass peak in the \( dp \rightarrow ^3\text{He} X \) reaction. For this purpose the experiment was carried out at twelve closely spaced deuteron momenta a little above the \( \eta \) threshold and two just below to provide the information required to subtract the multipion background. By exploiting its full geometric acceptance near threshold, it was possible to calibrate the ANKE spectrometer very precisely and thus determine the final \( ^3\text{He} \) CM momentum \( p_f \) for each of the twelve deuteron beam momenta and the results are shown in Fig. 3. Although the method depends primarily upon the determination of the kinematics rather than counting rates, its implementation is helped enormously by the fact that the cross section jumps to its plateau value already by the first point in Fig. 3.

The long lever arm facilitates a robust extrapolation to the \( \eta \) threshold, where the deuteron momentum was found to be \( p_d = 3141.686 \pm 0.021 \) MeV/c. There is a one-to-one relation between this and the mass of the meson, which is found to be

\[
m_\eta = (547.873 \pm 0.005_{\text{stat}} \pm 0.026_{\text{syst}}) \text{ MeV}/c^2.
\]

It is in fact the determination of the threshold beam momentum that provides the largest contribution to the 26 keV/c\(^2\) systematic uncertainty. The result is compatible with all the modern measurements reported by the Particle Data Group that studied the \( \eta \) decay and the error bars are as small as any of these. The result suggests that earlier missing-mass determinations, which differed by \( \sim 0.5 \) keV/c\(^2\), lacked the necessary precision.

### III. THE NUCLEON-NUCLEON PROGRAMME

A good understanding of the nucleon-nucleon (\( NN \)) interaction still remains one of the principal goals of nuclear and hadronic physics. Apart from their intrinsic
importance for the study of nuclear forces, \(NN\) elastic scattering data are also necessary ingredients in the modeling of meson production and other nuclear reactions at intermediate energies. It therefore goes without saying that all facilities should try to fill in the remaining gaps in our knowledge in the area.

The COSY-EDDA collaboration [6] produced a wealth of data on proton-proton elastic scattering that completely revolutionised the isospin \(I = 1\) \(NN\) phase-shift analysis up to about 2.1 GeV [11]. However, for proton energies above about 1 GeV, very little is known about the \(pp\) elastic differential cross section or analysing power for centre-of-mass angles \(10^\circ < \theta_{\text{cm}} < 30^\circ\). The cross section data that do exist seem to fall systematically below the predictions of the SAID partial wave analysis [11]. In this angular range the fast proton emerging at small angles from a hydrogen target can be measured well in the ANKE magnetic spectrometer, whereas the slow recoil proton emerging at large angles can be measured independently in one of the Silicon Tracking Telescopes. The luminosity that is so crucial for the determination of the absolute cross sections can be determined using the Schottky method [7] that was mentioned in the previous section. Preliminary data are already available on the differential cross sections at eight energies and approval has been given to measure the proton analysing powers at the same energies.

Much greater effort has been made in the study of the spin-dependent terms in large angle neutron-proton scattering. It was pointed out many years ago that the \(dp \to \{pp\},n\) charge exchange at small angles was very sensitive to the spin-spin terms in the \(np \to pn\) amplitude provided the excitation energy \(E_{pp}\) in the final \(pp\) system was kept low [12]. Under such conditions the \(\{pp\}\), is in a \(^1S_0\) state and the charge exchange necessarily involves a spin flip from the initial \(np\) spin-triplet of the deuteron. Furthermore, measurements of the deuteron tensor analysing powers \(A_{xx}\) and \(A_{yy}\) allow one to distinguish between the contributions from the three spin-spin \(np\) amplitudes.

Measurements were carried out at Saclay [13, 14] but only in regions where the \(nn\) amplitudes were reasonably well known. These have been extended in fine steps in momentum transfer \(q\) to higher energy at ANKE [15, 16]. A cut of \(E_{pp} < 3\) MeV was typically imposed but any contamination from triplet \(P\)-waves was taken into account in the theoretical modelling [17]. The ANKE analysing power results at 1.6, 1.8, and 2.27 GeV are compared in Fig. 4 to these impulse approximation predictions using up-to-date \(np\) amplitudes [11] as input. The satisfactory agreement at the two lower energies, and also in the values of the differential cross sections, shows that the theoretical description is adequate here.
Above about 1 GeV neutron-proton data become rather sparse. It comes therefore as no surprise that, when the same approach is employed on the higher energy data shown in Fig. 4, the current SAID amplitudes \cite{11} give a poor overall description of the results. However, if the longitudinal spin-spin amplitude is multiplied by a global factor of 0.75, the agreement is much more satisfactory. This is evidence that the charge exchange data can provide useful input to the $NN$ database.

Confirmation of these conclusions is to be found in the measurements of the deuteron-proton spin correlation parameters measured with the polarised hydrogen gas cell. Results on this are shown in Fig. 5. In impulse approximation, these are sensitive to the interference between the longitudinal spin-spin amplitude and the two transverse ones. Whereas there is satisfactory agreement with the theoretical predictions at 1.2 GeV, the model is much more satisfactory at 2.27 GeV if the longitudinal input is scaled by a factor of 0.75.

In addition to measuring the spin correlations with the polarised cell, data were also obtained on the proton analysing power in the $d\vec{p} \to \{pp\}, n$ reaction and the results are shown in Fig. 6. The message here is very similar to that for the other observables. At 600 MeV per nucleon the SAID input reproduces the experimental points very well but it seems that at 1135 MeV the SAID description of the spin-orbit amplitude has serious deficiencies.

As well as studying the $d\vec{p} \to \{pp\}, X$ reaction at 2.27 GeV as a function of the transverse momentum transfer. The data are integrated over the mass range $1.19 < M_X < 1.35$ GeV/$c^2$ \cite{18}. The first indications shown in Fig. 7 are that the Cartesian analysing powers are largely opposite in sign to those for $\vec{d} p \to \{pp\}, n$ \cite{18}. These data will therefore yield information on the amplitude structure of the $NN \to N\Delta$ reaction.
IV. PION PRODUCTION IN NUCLEON-NUCLEON COLLISIONS

One of the priorities at ANKE is to perform a complete set of measurements of \(NN \rightarrow (pp)_s\pi\) at low energy. Since, as in Sec. III, the \((pp)_s\) proton-proton pair is overwhelmingly in the \(1^S_0\) state, only the polarisations of the initial nucleons have to be studied. As parts of this programme, the differential cross section and analysing power of the \(\vec{pp} \rightarrow (pp)_s\pi\) reaction were measured at 353 MeV [19] and the same observables measured in quasi-free \(\pi^-\) production on the deuteron, \(\vec{pd} \rightarrow p{pp}_s\pi^-\) [20], where \(p_{sp}\) is a “spectator” proton. By making certain theoretical assumptions and retaining amplitudes up to pion d-waves, the combined data sets are sufficient for a partial-wave decomposition. This is of particular interest for Chiral Perturbation Theory, where it is important to establish that the same short-ranged \(NN \rightarrow NN\pi\) vertex that contributes to p-wave pion production is consistent with other intermediate energy phenomena.

For \(\pi^0\) production, both protons were measured in the ANKE Forward Detector. After selecting the \(1^S_0\) final state, the kinematics of the \(pp \rightarrow (pp)_sX\) process could be reconstructed on an event-by-event basis to obtain the \(\pi^0\) rate from the missing-mass \(M_X\) spectrum. By using a beam with a \(\pm 68\%\) polarisation, the cross section and analysing power could be measured simultaneously and the results are shown in Figs. 8 and 9.

![Graph](image1)

**FIG. 8:** Differential cross section for the \(pp \rightarrow (pp)_s\pi^0\) reaction at 353 MeV. The ANKE measurements (solid black) circles are compared with the CELSIUS data (open red) circles at 360 MeV [21]. The curve is the partial wave fit.

The cross section data agree quite well over most of the angular range with those taken at CELSIUS [21] and the strong anisotropy is evidence for significant d-wave pion production. In the absence of pion d- (or higher) waves the analysing power would vanish and, as seen in Fig. 8, this is far from being the case.

In the \(\vec{pd} \rightarrow p(\pi^-)_s\pi^-\) experiment, three particles had to be detected in the final state to identify the reaction. In addition to the two protons in the \(1^S_0\) state, either the \(\pi^-\) or the third (slow) proton must be measured, the latter in one of the silicon tracking telescopes placed in the target chamber. Together the two detection modes led to a full angular coverage. In either case the slow proton was restricted kinematically to be a spectator so that the cross section and analysing power of the quasi-free \(\vec{pn} \rightarrow (pp)_s\pi^-\) reaction could be extracted in the 353\(\pm 20\) MeV interval, the results being shown in Figs. 10.

![Graph](image2)

**FIG. 9:** (a) Product of the measured analysing power and differential cross section for the \(\vec{pp} \rightarrow (pp)_s\pi^0\) reaction. (b) Measured values of \(A_y\); the overall systematic uncertainty is \(\approx 5\%\). The curves are partial wave fits.

![Graph](image3)

**FIG. 10:** Differential cross section for \(pn \rightarrow (pp)_s\pi^-\) at \(T \approx 353\) MeV. ANKE data with statistical errors are shown by red circles; the systematic error is \(\approx 6\%\). The statistical errors of the TRIUMF data [22] (green triangles) are smaller than the symbols and the normalisation uncertainty is 10\%. The blue stars are arbitrarily scaled cross sections extracted from pion absorption data [24]. The solid curve is a partial wave fit.
and [11].

The differential cross section agrees with the earlier TRIUMF measurement [22], except for their two most forward points. The disagreement persists with the analysing power data measured in the forward hemisphere [29] shown in Fig. 11. On the other hand, the agreement with the shape of the cross section deduced from the \( \pi^{-}{ }^{3}\text{He} \rightarrow pnn \) reaction [23] is even better.

\[ A_\gamma \frac{\partial \sigma}{\partial \Omega} \text{[}\mu b/sr]\]

Even if one considers only \( s \), \( p \), and \( d \)-wave pion production, the cross section and analysing power data are insufficient to perform a full amplitude analysis without further assumptions. These were to neglect the coupling between the initial \( ^3P_2 \) and \( ^3F_2 \) waves and to use the Watson theorem to determine the phases of the production amplitudes from these and also the \( ^3P_0 \) wave. There are then seven real parameters available to describe essentially ten features in Figs. 8–11. The success achieved here suggests that the phase assumptions are basically correct. The analysis shows that \( d \)-wave production is confined almost purely to the \( ^3P_0 \) channel but by far the largest term is associated with \( p \)-wave production from the initial \( ^3D_1 \) state.
