(Received October 13, 2001)

Summary (−)-Hydroxycitrate (HCA) is known to inhibit increasing malonyl CoA concentration during endurance exercise. Furthermore, a short-term administration of HCA enhances endurance exercise performance in mice. Therefore we investigated the short-term administration of HCA on the exercise performance of athletes. Subjects were administered 250 mg of HCA or placebo as a control (CON) for 5 d, after each time performing cycle ergometer exercise at 60% VO\textsubscript{2}max for 60 min followed by 80% VO\textsubscript{2}max until exhaustion. Blood was collected and expired gas samples analyzed at rest and every 15 min. The respiratory exchange ratio was significantly lower in the HCA trial than in the CON trial (p<0.05). Fat oxidation was significantly increased by short-term administration of HCA, and carbohydrate oxidation was significantly decreased (p<0.05) during exercise, presumably resulting in increasing the cycle ergometer exercise time to exhaustion after 1 h of 60% VO\textsubscript{2}max exercise (p<0.05). These results suggest that a short-term administration of HCA enhances endurance performance with increasing fat oxidation, which spares glycogen utilization during moderate intensity exercise in athletes.

Key Words (−)-hydroxycitrate (HCA), endurance performance, respiratory exchange ratio, carbohydrate oxidation

Many dietary supplements are used to increase exercise performance on the athletic field (1). Coaches and athletes expect that these supplements might compensate for a lack of training (2). Actually, several studies revealed that of most importance might be the sparing effect of glycogen utilization during exercise through an increase in the ability of skeletal muscle to oxidize lipids (3, 4).

There has been much researches and unpublished observations over the past decades demonstrating the importance of muscle and liver glycogen in reducing fatigue and improving athletic performance. This is because when muscle glycogen and blood glucose concentrations are low, the intensity of exercise must be reduced to a level that can be supported by the body's limited ability to convert body fat into energy (5). Focusing on these suggestions, many researchers (6–8) have reported that caffeine has a positive ergogenic effect. They proposed that it is achieved by an elevation in catecholamines, which enhance fat oxidation either by increasing free fatty acid (FFA) levels or by intramuscular triacylglycerol lipolysis (6). Blood FFA was elevated 1 h after caffeine ingestion in some studies (9–11). We have suggested that many kinds of supplements such as caffeine (8, 10), capsaicin (12, 13), red pepper (14, 15), and carnitine (16) affected the endurance performance in animals and athletes.

Recently, (−)-hydroxycitrate (HCA) has become known to reduce body fat accumulation after a few weeks of ingestion (17). HCA, a potent inhibitor of ATP citrate-lyase (EC 4.1.3.8), inhibits fatty acid synthesis and reduces appetite in rodents (18). It inhibits citrate conversion into acetyl CoA in cells as a result of acetyl CoA convert into malonyl CoA; therefore fat oxidation may increase in skeletal muscle during endurance exercise performance (2). Malonyl CoA is an inhibitor of carnitine palmitoyltransferase I, the enzyme that controls the oxidation of fatty acids by regulating their transfer into the mitochondria. We hypothesized that during prolonged endurance exercise, carbohydrate oxidation was increased by acetyl CoA conversion into malonyl CoA, which caused fatigue in athletes. We reported that a short-term administration of HCA promotes fat oxidation and spares carbohydrate utilization in mice at rest and during exercise (2). However, there is little evidence of its effectiveness in humans.

In this paper we present evidence on whether short-term ingestion of HCA increases fat oxidation that results in carbohydrate sparing and enhances endurance exercise performance in athletes.
METHODS

Subjects. Six elite male athletes agreed to participate in the study after being informed of the nature of the experiments. The subjects were nonsmokers and had been training 6 d a week and participating in competitive matches several times a year. They have been training at least 6 h/d for 5 d/wk. They were living in a dormitory and had the same diet contents 3,500 kcal/d. Their characteristics: 19.33 ± 0.82 y old, 177.80 ± 3.70 cm tall, 72.88 ± 3.85 kg weight, and 10.63 ± 0.91% of body fat (Table 1). Each subject signed a consent form that outlined possible risks of the procedure. The protocol was approved by Institute of Natural Sciences of Taegu University in accordance with the Helsinki Declaration of 1975.

Experimental procedure. Subjects reported to the laboratory before the start of the experiment for an incremental maximum oxygen consumption (VO2max) test on a cycle ergometer as reported by Lim et al. (14). Their mean VO2max was 59.91 ± 3.85 mL·kg⁻¹·min⁻¹. We calculated their exact 60% and 80% of VO2max exercise bout based on their VO2max.

The subjects were requested to maintain similar training patterns throughout the duration of the experiments. Moreover, they were requested to consume the same diets from the first day of the experiment to the end, except for HCA (Soluble type; Nippon-Shinyaku Co., Japan). Two tablets, each containing 125 mg of HCA, had to be taken just after breakfast or lunch 5 d/wk. The same amount of a flour tablet was used as control (CON) for 5 d/wk. During the experimental periods, the subjects were educated to avoid sources of methylxanthines such as tea, coffee, chocolate, cola, and caffeine-containing over-the-counter pharmaceuticals. The HCA or placebo was ingested for 5 d in a double-blind manner. At least 2 d between trials were established to minimize any possible effects of the HCA.

Table 1. Physical characteristics of the subjects.

| Age (y) | 19.3 ± 0.8 |
| Height (cm) | 177.8 ± 3.7 |
| Body weight (kg) | 72.9 ± 3.9 |
| Body fat (%) | 10.6 ± 0.9 |
| VO2max (mL/kg/min) | 59.9 ± 3.9 |

Values are mean ± SE. * Body fat was analyzed by a body fat analyzer (TBF-105, Tanita, Japan).

Experimental design. The protocol for each trial was designed in the same method. Subjects reported to the laboratory 2 h before the start of the experiment (09:00). They ingested a 640-kcal meal (bread, eggs, orange juice) and the HCA or CON 2 h before the exercise as reported previously (8). After the meal, the subjects were allowed to rest in a seated position. After resting for 100 min, they warmed up with 10 min of stretching exercises 20 min before exercise. During the resting periods, a venous 3-way catheter was inserted into the antecubital vein and was kept patent with a saline infusion. A resting blood sample and expired gas were collected and analyzed.

The subjects exercised by the use of a bicycle ergometer (Recocor, LODE Medical, Netherlands) at a pedaling frequency of 50 rpm and an intensity of 60% of VO2max for 60 min; the intensity was then elevated to 80% until exhaustion. The two-intensity exercise (60% for 60 min and 80% VO2max exercise until exhaustion) protocol is to investigate endurance performance (8, 10).

Samples for expired air were analyzed every 5 min for 60 min at 60% of their VO2max and for 5 min at 80% VO2max. Blood samples (5 mL) were taken every 15 min for 60 min of the exercise at 60% VO2max and 5 min of 80% VO2max. The investigator determined exercise time to exhaustion when the revolution could no longer be maintained three times at 50 rpm of pedaling. The rate of perceived exertion (RPE) was requested every 5 min for 65 min of the exercise bout. The subjects had no indication of time after the 65 min sampling period until exhaustion. The procedures of the experiment were performed in a laboratory chamber with a room temperature of 20°C and humidity of 50%. The experimental design is shown in Fig. 1.

Analysis. Expired gas samples were analyzed on an O2/CO2 Auto-analyzer (QUARK PFT, COSMED, Italy) previously calibrated for O2 and CO2. Fat and carbohydrate oxidation during exercise was calculated as previously described (2). The oxygen consumption (VO2), carbon dioxide exhaustion (VCO2), RER, carbohydrate oxidation, and fat oxidation was calculated as follows:

\[ VO_2 = \left( \frac{FEN_2 - FIN_2}{FIO_2 - FEO_2} \right) \cdot Ve, \]
\[ VCO_2 = (FECO_2 - FICO_2) \cdot Ve, \]
\[ RER = VCO_2 / VO_2, \]
\[ \text{Carbohydrate oxidation} = (4.51 \cdot RER - 3.18) \cdot VO_2, \]

Fig. 1. Experimental design.
Fat oxidation = 1.67 * (1 – RER) * VO₂

FE₂N, concentration of nitrogen in the exhaust air; FIN₂, concentration of nitrogen in the room air; FEO₂, concentration of oxygen in the exhaust air; FIO₂, concentration of oxygen in the room air; FECO₂, concentration of carbon dioxide in the exhaust air; FICO₂, concentration of carbon dioxide in the room air; Ve, ventilation corrected to standard temperature and pressure.

Blood samples were collected with a heparinized tube. Whole blood 500 µL was immediately separated into a microcentrifuge tube for blood glucose and lactate analyses by the use of an autoanalysis system (YSI 2300 Plus, Yellow Springs Institute, USA). Another blood sample was centrifuged, and plasma was collected and stored in a −70°C freezer for future analysis.

Plasma FFA (NEFAzyme-Kit, Eiken, Tokyo, Japan) and glycerol (Boehringer Mannheim, Gmbh., Germany) concentrations were determined by enzymatically using a kit as previously described by Lim et al. (14).

Statistical analysis. The results are described as mean ± SE. The data were analyzed with a two-way ANOVA repeated measure. Exercise time (12 time points) and supplementation type (Placebo and HCA) were the independent variables. Significant differences between means were determined with a Newman-Kuels post hoc test. The level of significance was set at p<0.05.

RESULTS

Oxygen consumption

The ingestion of the 250 mg HCA for 5 d did not affect VO₂ at rest or during the 60% VO₂max ergometer exercise for 60 min (Fig. 2A). However, it produced a slight increase in VO₂ at 60 min and 65 min of 80% VO₂max, but it was not significant.

Respiratory exchange ratio (RER)

The RER was significantly lower in the HCA trial than in the CON trial throughout the exercise (Fig. 2B).

Substrate oxidation

The carbohydrate oxidation decreased significantly in the HCA trial from 10 min to 65 min of the exercise (Fig. 3A). And the fat oxidation significantly increased in the HCA trial at the same period (Fig. 3B).
Table 2. Changes of blood substrates during moderate- to high-intensity cycle ergometer exercise with and without HCA.

| Blood measurements          | Exercise time (min) | Glucose (mmol/L) | Lactate (mmol/L) | FFA (mmol/L) | Glycerol (mmol/L) |

Values are mean and SE.
* Statistically significant from control at $p<0.05$, respectively.

**Blood measurements**

The blood glucose concentration was not significantly different at rest or during exercise between the trials, excepting 45 min of exercise (Table 2).

The blood lactate level was not significantly changed by HCA ingestion during 60% VO$_{2max}$ exercise, but it was lower in the HCA trial when the exercise intensity increased to 80% VO$_{2max}$ at 65 min of the exercise (Table 2).

Plasma FFA levels were not higher in the HCA trial during the 60% VO$_{2max}$ exercise, though fat oxidation was higher in the HCA trial. However, it was significantly higher in the HCA trial than in the CON trial when exercise intensity was increased to 80% VO$_{2max}$ at 65 min of the exercise.

Plasma glycerol concentration during the exercise was not significantly affected by the HCA ingestion (Table 2).

**Ratings of perceived exertion (RPE)**

RPE was significantly lower in the HCA trial from 15 min of the 60% VO$_{2max}$ exercise to exhaustion (Fig. 4). Moreover, it was significantly lower in the HCA trial than in the CON trial when the exercise intensity increased to 80% VO$_{2max}$ ($p<0.05$).

**Endurance capacity**

Exercise time to exhaustion at 80% VO$_{2max}$ after 60% VO$_{2max}$ for 60 min was significantly longer in the HCA trial than in the CON trial (Fig. 5).

**DISCUSSION**

The aim of the present study was to investigate the effects of the HCA short-term ingestion on endurance exercise performance in athletes. We show in this study that an ingestion of 250 mg HCA for 5 d increases fat oxidation and decreases the ratings of perceived exertion resulting in an improvement of endurance performance.

Interests in this kind of study are aroused by the possibility of enhancing endurance exercise, by using ergogenic supplements, such as sports beverages, caf-
RCA has an inhibiting effect on carbohydrate oxidation and ingestion might postpone a lactate threshold (LT), since utilized as the energy source during moderate-intensity exercise. These findings suggest that by the short-term ingestion of RCA during exercise, VO2max exercise, however, lactate concentration was significantly changed by the RCA ingestion. In an 80% VO2max exercise, clearly VO2max exercise, suggesting that by short-term RCA ingestion, fatty acids were used more as an energy source than they were reesterified in the adipocytes during moderate-intensity exercise.

An acute administration of RCA did not affect energy substrate utilization more (2, 21, 22). However, chronically administered HCA affects the RER, which was lower during the 60 min running period, and lipid oxidation was significantly greater and carbohydrate oxidation was significantly less than the control trial (2). In the present study, as shown in Fig. 2B, RER in the RCA trial was significantly lower than in the CON trial, even though similar concentrations of serum FFA and glycerol (Table 2). Furthermore, fat oxidation (Fig. 4B) was significantly higher in the HCA at a similar time point of RER, but carbohydrate oxidation showed a reverse result of fat oxidation (Fig. 4A). It might be suggested that HCA suppressed stored glycogen utilization during moderate-intensity exercise. This spared glycogen might be used effectively at the latter stage of endurance exercise. Actually, our experimental protocol was composed of two different exercise intensities at 60% VO2max for 1 h followed by 80% VO2max until exhausted. These two intensities showed the effects of glycogen sparing during prolonged endurance exercise performance. These RER, fat oxidation, and carbohydrate oxidation data at 80% VO2max exercise also showed higher fat oxidation.

The enhancement of fat oxidation at the early stage of exercise could lead to increased endurance exercise capacity. In the present study, the ergometer exercise time to exhaustion was significantly delayed 2.37 min after 1 h of 60% VO2max exercise in the RCA trial. The promotion of fat oxidation with a short-term administration of HCA may be attributed to the activity of carnitine palmitoyltransferase I (CPT I), which plays an important role in regulating the flux of long-chain fatty acids into the mitochondrial membrane to oxidation (26). Malonyl CoA inhibits CPT I activity in the cytosol, but its effect was suppressed by HCA, as discussed above.

In summary, the short-term administration of HCA enhanced fatty acid utilization and less accumulation of lactate during exercise at the two different intensities. Moreover, HCA administration significantly reduced the RER and enhanced fat oxidation during moderate-intensity exercise. Increased fat oxidation reduced the carbohydrate oxidation during the first stage of exercise. These results suggest that an enhancement of fat oxidation and endurance-exercise capacity by a short-term administration of HCA in athletes might have glycogen-sparing effects during moderate-intensity exercise.
