ABSTRACT

We present constraints on the nature of the first galaxies selected at 350 μm. The sample includes galaxies discovered in the deepest blank-field survey at 350 μm (in the Boötes Deep Field) and also later serendipitous identifications in the Lockman Hole. In determining multiwavelength identifications, the 350 μm position and map resolution of the second generation Submillimeter High Angular Resolution Camera are critical, especially in the cases where multiple radio sources exist and the 24 μm counterparts are unresolved. Spectral energy distribution templates are fitted to identified counterparts, and the sample is found to comprise IR-luminous galaxies at 1 < z < 3 predominantly powered by star formation. The first spectrum of a 350 μm selected galaxy provides an additional confirmation, showing prominent dust grain features typically associated with star-forming galaxies. Compared to submillimeter galaxies selected at 850 and 1100 μm, galaxies selected at 350 μm have a similar range of far-infrared color temperatures. However, no 350 μm selected sources are reliably detected at 850 or 1100 μm. In our sample with redshifts 1 < z < 2, the first galaxy selected at higher redshifts show a large dispersion in their mid- to far-infrared colors. This implies a limit to which the mid-IR emission traces the far-IR emission in star-forming galaxies. The 350 μm flux densities (15 < S350 < 40 mJy) place these objects near the Herschel/SPIRE 350 μm confusion threshold, with the lower limit on the star formation rate density suggesting the bulk of the 350 μm contribution will come from less luminous infrared sources and normal galaxies. Therefore, the nature of the dominant source of the 350 μm background—star-forming galaxies in the epoch of peak star formation in the universe—could be more effectively probed using ground-based instruments with their angular resolution and sensitivity offering significant advantages over space-based imaging.

Key words: galaxies: high-redshift – galaxies: starburst – infrared: galaxies – submillimeter

Online-only material: color figures

1. INTRODUCTION

Submillimeter-selected galaxies (SMGs) were discovered in pioneering lensed and blank-field surveys (e.g., Smail et al. 1997; Barger et al. 1998; Eales et al. 1999) with the 850 μm optimized Submillimeter Common User Bolometer Array (SCUBA; Holland et al. 1999) and later in similar surveys with millimeter detectors (e.g., MAMBO, BOLOCAM, etc.; Bertoldi et al. 2000; Laurent et al. 2005). SMGs mainly comprise massive, star-forming galaxies (see, e.g., Fox et al. 2002) and are part of the IR-luminous far-IR galaxy population, which includes galaxies found in the local universe by the Infrared Astronomical Satelite (IRAS) All Sky Survey (Soifer et al. 1984; Joseph & Wright 1985; Soifer et al. 1987) and other galaxies detected in mid- and far-IR bands, most notably (in terms of number selected) with the Infrared Space Observatory (Kessler et al. 1996), the Spitzer Space Telescope (Werner et al. 2004), and the Akari Infrared Satellite (Murakami et al. 2007) out to z ∼ 2 (see, e.g., Rowan-Robinson et al. 1997; Puget et al. 1999; Aussel et al. 1999; Elbaz et al. 2002; Chary et al. 2004; Lonsdale et al. 2004; Le Floc’h et al. 2004, 2005; Yan et al. 2004; Matsuhara et al. 2006).

The majority of SMGs have been selected at long submillimeter–millimeter bands (500–1300 μm). Shorter submillimeter wavelengths (200–500 μm) are more demanding for ground-based observers. For example, on a good night at Mauna Kea, atmospheric transmission is about ∼30% at 350 μm but >80% at 850 μm (Serabyn et al. 1998). Despite this, the first galaxy selected purely by 350 μm emission—SMM J143206.65+341613.4 (=SSG 1, Short Submillimeter Galaxy 1)
was discovered (Khan et al. 2005) in a deep, blank survey of the Bo"otes Deep Field with the second generation Submillimeter High Angular Resolution Camera (SHARC II; Dowell et al. 2003; Moseley et al. 2004) along with a second detection, SMM J143206.11+341648.4 (=SSG 2; Khan et al. 2007). This survey, reaching 13 mJy and currently the deepest at 350 μm, obtained the first constraints on the 350 μm source counts. Three additional 350 μm selected galaxies have been found in serendipitous SHARC II follow-up observations of 850 μm and 1100 μm SMGs in the Lockman Hole (Laurent et al. 2006; Coppin et al. 2008).

Short-wavelength submillimeter surveys are expected to principally select star-forming galaxies at 1 < z < 3 (see, e.g., Pearson & Khan 2009; Khan et al. 2007; Khan et al. 2006), the epoch of peak star formation in the universe (e.g., Hopkins & Beacom 2006). Source count models that reproduce the observed 350 μm counts include a predominantly IR-luminous galaxy population evolving with redshift (e.g., Pearson & Khan 2009; Franceschini et al. 2009), but more observations are needed to verify these predictions.

This paper presents a detailed characterization of each of the five 350 μm selected galaxies following the approach of Khan et al. (2005). Multifrequency data are presented, and spectral energy distribution (SED) template fitting is used to provide constraints on the photometric redshifts, thermal parameters (IR luminosity and dust temperature), and energy diagnostics. Additionally, the first mid-IR spectrum of a 350 μm selected galaxy, obtained using Spitzer’s Infrared Spectrograph (Houck et al. 2004), is given. The properties of the sample are compared with 850 and 1100 μm selected SMGs. Table 1 identifies the five sources and includes short nicknames used for convenience. The WMAP first year cosmological parameters ($H_0 = 71$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.27$, $\Omega_A = 0.73$; Bennett et al. 2003) are used throughout this work.

### 2. OBSERVATIONS, DATA REDUCTION, AND COUNTERPART IDENTIFICATION

#### 2.1. Observations

The SHARC II observations, data reduction, and source extraction procedure for the Bo"otes Deep Field survey are discussed in detail by Khan et al. (2007). Further details of source extraction are given by Khan (2006). Monte Carlo simulations for determining the survey completeness also provide a measure of the flux boosting. Approximately, 4000 artificial sources of random intensity and position were inserted into the raw data map, then extracted using the same procedure as for the real sources (Khan et al. 2007). For recovered $\geq 3\sigma$ sources with input flux densities $> 15$ mJy, the ratio of the measured flux density to the input flux density indicates that the average flux boosting is $1.07 \pm 0.23$. Given the multiwavelength confirmation on SSG 1 and SSG 2, low outliers can be ruled out. Therefore, we proceed without applying a correction factor to these sources and assume that this also holds for the sources in the Lockman Hole. For the Lockman Hole, published 350 μm flux densities were combined with public $B$, $R$, $I$, and $z$ photometry from the Subaru Lockman Hole survey (Dye et al. 2008), $K$ band imaging from UKIDSS (Lawrence et al. 2007), archival Spitzer IRAC (Fazio et al. 2004) and MIPS (Rieke et al. 2004) imaging, and 1.4 GHz data from Biggs & Ivison (2006). These compiled photometric data are presented in Table 2.

### Table 1

| IAU Name         | Nickname | Other name | VLA Position (J2000) | 350 μm Position (J2000) |
|------------------|----------|------------|---------------------|-------------------------|

Notes.

VLA positions are for VLA counterparts as identified in this paper. IAU names are based on 350 μm positions.
The Spitzer/IRS observation of SSG 1 was designed according to the recommended SSC setup. For each slit, there were six pointings along the slit at 24μm spacing, all centered on the slit in its narrow dimension. This is equivalent to the normal point source method except that the target is observed in six different slit positions instead of the usual two, lessening the effects of flat-fielding errors and bad pixels. In 3.1 hr (the total for the AOR, including peakups and overheads), there were five cycles of LL1 (19.5–38.0μm) and seven of LL2 (14.0–21.3μm) with 120 s ramps at each of the six slit positions. The data were reduced using the pipeline S15, cleaned using irsclean, and extracted with smart (Higdon et al. 2004). Two extraction techniques were compared: the first method involved extracting the spectra from the individual images and taking the median spectrum; the second method was to align the images, and then extract the spectrum. There was little difference in the final spectrum using either technique, and the spectrum is shown in Figure 1. The most prominent features in the SSG 1 spectrum are due to polycyclic aromatic hydrocarbons (PAHs). For quantitative analysis, PAHs can be measured from integrating the flux above a baseline, but this method tends to underestimate the flux density as compared to a profile decomposition method such as the one used by PAHfit (Smith et al. 2007; see also Galliano et al. 2008 for more detailed consideration of the two approaches). While both methods give similar PAH ratios and similar spatial variations of PAH strengths, absolute flux densities will differ due to assumptions about the PAH profiles.

2.2. Counterpart Identification

The additional 24μm and 1.4 GHz imaging of the Boötes field yielded counterparts in these bands for SSG 1 and 2 with low probabilities of chance association (Khan et al. 2007). The more precise positions were then used to identify optical and mid-IR counterparts. Finding counterparts for the three sources in the Lockman Hole is not straightforward: Figure 2 shows thumbnail images of the fields at various wavelengths. As can be seen, there exist multiple radio detections for two of the 350μm objects. However the most likely counterparts can be determined with the following rationale.

1. LH 350.J. The 1.4 GHz image shows two potential counterparts, but only the southern one is within the 9σ SHARC II beam. In the visible images this appears to be a blend of two sources. The photometric redshift for this southerly source was obtained using hyper-z (Bolzonella et al. 2000) in conjunction with the BRzJK [3.6][4.5] photometry, similar to the approach of Dye et al. (2008). The best-fitting solution is a starburst template at z = 1.19±0.33. The northern 1.4 GHz object is not associated with any visible-light detection, although it is prominent in the IRAC and MIPS images. Those images also show two more sources: an eastern object whose SED suggests it is a star or a low-redshift
elliptical galaxy, and well to the west, the QSO RDS 054A at \( z = 2.416 \) (Schmidt et al. 1998), which is not expected to make a strong contribution to the 350 \( \mu \text{m} \) emission.

2. **LH 350.2.** The 1.4 GHz image shows three sources within the beam. However, the two outermost objects are well resolved in the visible imaging, suggesting that they are likely to be relatively nearby. Photo-z fitting puts both at \( z \sim 0.4 \), and SED template fitting puts a contribution to the 350 \( \mu \text{m} \) emission of \(<20\%\) (assuming a dust temperature, \( T_d > 30 \text{ K} \)). Therefore, the very red middle object is likely to be the dominant source of the 350 \( \mu \text{m} \) emission with a best-fitting photo-z of \( 1.21^{+0.13}_{-0.20} \).

3. **LH 350.3.** There is a strong 24 \( \mu \text{m} \) and weak 1.4 GHz source within 6\( ''\) of the 350 \( \mu \text{m} \) position. The \( B \) through 4.5 \( \mu \text{m} \) images suggest that the mid-IR flux is a combination of two sources with the radio position lining up on the redder, western object. Best-fitting photometric redshifts are \( z = 2.47^{+0.51}_{-0.95} \) and \( z = 0.56^{+0.26}_{-0.30} \) for the western and eastern objects, respectively. There remains the possibility of a merging system because the secondary solution for the eastern source is \( z = 2.60^{+0.32}_{-0.33} \). Based on the radio identification, the western object is taken as the main source of the submillimeter emission.

### 3. CONSTRAINTS ON THE PHOTOMETRIC REDSHIFT AND THERMAL EMISSION

The multiwavelength photometry in Table 2 was used to derive photometric redshifts and thermal emission parameters. Following the same approach as Khan et al. (2005), the STARDUST2 template fit was used (P. F. Chialin 2009, in preparation) to simultaneously obtain the photometric redshift \( z_{\text{phot}}\), dust temperature \( T_d\), and the 8–1000 \( \mu \text{m} \) IR luminosity \( L_{\text{IR}}\). Templates were based on local starbursts, and \( \chi^2 \) was minimized through a Levenberg–Marquardt technique. For SSG 1, the redshift obtained for the IRS spectrum in Figure 1 was used in the fit, but \( z_{\text{spec}} = 1.05 \) agrees well with the \( z_{\text{phot}} = 1.03 \) from the template fitting. The best-fit parameters are given in Table 3, and the best-fitting templates are shown in Figure 3.

For SSG 1, SSG 2, and LH 350.3, the 350 \( \mu \text{m} \) flux density is well fitted by the template, but in the cases of LH 350.2 and 3, the quality of the fit at 350 \( \mu \text{m} \) is clearly affected by the longer submillimeter data, which constrain the slope on the Rayleigh–Jeans side of the spectrum. Additionally, the 24 \( \mu \text{m} \) flux density is useful in determining which side of the peak the 350 \( \mu \text{m} \) data point lies. Usually, the mid-IR is not used to constrain the rest-frame far-IR continuum emission because specific dust grains...
and active galactic nuclei (AGNs) can have a major effect on mid-IR flux densities. Usage of the MIPS band was checked for a sample of SMGs (from Coppin et al. 2008) by comparing template fits using measurements at 350 \( \mu m \), 850 \( \mu m \), and radio with measurements at 24 \( \mu m \), 350 \( \mu m \), and radio plus long-submillimeter limits. The two approaches agree within the \textsc{stardust2} uncertainties. This indicates our thermal parameters are not noticeably biased by the inclusion of the mid-IR data (see P. F. Chanial 2009, in preparation, for more details).

For LH 350.3, the lack of a defining 1.6 \( \mu m \) rest-frame stellar continuum feature makes a significant AGN contribution plausible, although the relatively low radio flux density would argue against this. Because of the absence of AGN templates in \textsc{stardust2}, the LH 350.3 data were also fitted using another routine with a mixture of AGNs and starburst templates (Negrello et al. 2009). In this template fit, the favored solution is a starburst at \( z_{\text{phot}} = 3.8 \) (but without including the radio flux density). Therefore, we consider LH 350.3 to be, like the rest of this sample, predominantly star forming. Given the photometric redshift estimates from hyper-z, \textsc{stardust2}, and Negrello et al. (2009), it is possible that LH 350.3 is the most distant galaxy so far discovered at short-submillimeter wavelengths.

### 3.1. Energy Source Diagnostics

As can be seen in Figure 3, all five sources are well fitted in the mid-IR by templates that include features associated with star formation, i.e., a rest-frame 1.6 \( \mu m \) stellar continuum bump and apparent PAH emission. For SSG 1, the presence of PAH is confirmed by the mid-IR spectrum, as shown in Figure 1. An emission line from [Ne II] is likely present though blended with possible PAH emission at 12.7 \( \mu m \). The dust continuum is relatively flat until (rest wavelength) \( \sim 15.5 \mu m \). Although the 9.7 \( \mu m \) silicate absorption is relatively weak, it is within the range seen in local IR-luminous galaxies. Table 4 gives the emission feature fluxes, and a standard template (IRAS 22491–1808, an IR-luminous galaxy with moderately strong PAH emission) was used to obtain an overall best-fitting redshift from the spectral features of 1.05±0.01.

The values of \( L_{\text{PAH}} \) for the 7.7 and 11.3 \( \mu m \) rest-frame emission (6.8 and \( 2.0 \times 10^9 \) \( L_\odot \)) are consistent with the \( L_{\text{PAH}} \) versus \( L_{\text{IR}} \) distribution of Pope et al. (2008) for a sample of 850 \( \mu m \) selected SMGs. (This comparison used the integrated line flux densities with the \( L_{\text{IR}} \) given in Table 3.) The 7.7 \( \mu m \) PAH luminosity also provides an estimate of the star formation rate (SFR) of 340 \( M_\odot \) yr\(^{-1}\) following the relation given by Weedman & Houck (2008). Given the strong star-forming features in the mid-IR spectrum, this compares favorably with the SFR derived from \( L_{\text{IR}} \) of 136 \( M_\odot \) yr\(^{-1}\) following the relation given by Kennicutt (1998).

### 4. DISCUSSION

The different survey depths make it complicated to produce fair statistics for number counts. The Lockman Hole surveys (Laurent et al. 2006; Coppin et al. 2008) were targeted at known sources, and sensitivity for serendipitous sources varied with distance from the target source. Even the blank field survey in Boötes had sensitivity varying with location (see Figure 3 of Khan et al. 2007). However, simply considering the flux densities of the five detections and the total survey area (15.1 arcmin\(^2\)),\(^{17}\) we estimate resolving \( \sim 20\% \) of the 350 \( \mu m \) contribution to the cosmic infrared background (CIB; Fixsen et al. 1998) at \( S > 17 \) mJy. This fraction is reasonable given that the bulk of the background will be generated by galaxies near the break in the differential counts. It is also consistent with the 30\% estimate at \( S > 13 \) mJy from the source counts of Khan et al. (2007).

A lower limit on the star formation rate density (SFRD) can be found using the thermal parameters in Table 3 and the

---

\(^{17}\) 5.8 arcmin\(^2\) for the Boötes observations; for LH 350.1 and 2 (Laurent et al. 2006) the map area is assumed to be that of the arguably similar \textsc{shades} observation of LH 350.3 of 3.1 arcmin\(^2\) (Coppin et al. 2008).
comoving volume in $1 < z < 3$. The conversion from far-IR luminosity to SFR is given by Kennicutt (1998). The result for this epoch is $0.017 \ M_{\odot} \ yr^{-1} \ M_{\text{pc}}^{-3}$, much lower than the values presented by Hopkins & Beacom (2006). This implies that the bulk of the 350 $\mu$m contribution to the SFRD is from less luminous infrared galaxies and normal galaxies, consistent with observations of IR-luminous galaxies in different bands (e.g., Le Floc’h et al. 2005) and the predictions from source count models (e.g., Pearson & Khan 2009).

Our 350 $\mu$m selected galaxies can be compared with sources selected at longer submillimeter wavelengths. Suitable samples that include 350 and 24 $\mu$m photometry come from Coppin et al. (2008), Laurent et al. (2006), and Kovács et al. (2006). The photometric redshifts and thermal parameters for these SMGs were again found using stardust2. Where there is no spectroscopic redshift, the photo-$z$ was obtained from optical and mid-IR magnitudes given by Dye et al. (2008) and Clements et al. (2008). Following the $L_{\text{IR}}-T_d$ distribution by Blain et al. (2004), there appear to be two trends separating the predominantly local IRAS galaxies from the higher redshift SMGs (see Figure 4). Compared with those selected at 850 and 1100 $\mu$m, the 350 $\mu$m selected sources have similar dust temperatures and give no indication of temperature bias according to selection wavelength. Deeper 800–1000 $\mu$m imaging (e.g., with ALMA—Wootten & Thompson 2009) of the 350 $\mu$m selected population would provide a more direct comparison of any selection biases.

Mid-IR surveys to probe the $1 < z < 3$ galaxy population have the advantage of better angular resolution, aiding counterpart identification (and hence more reliable redshift estimation), but a significant disadvantage is that without further far-IR observations, constraints on the rest-frame far-IR thermal emission must be indirectly inferred. The 350:24 flux density–redshift distribution for the SHARC II 350 $\mu$m selected SMGs compared with the 850 and 1100 $\mu$m selected SMGs is shown in Figure 5 alongside colors from various templates from Efstathiou et al. (2000). The overall distribution suggests that all samples are drawn from the same IR-luminous galaxy population, and the good agreement with the templates suggests these are predominantly luminous and ultraluminous infrared galaxies.\footnote{18}

Studies of infrared galaxies are often limited by unavailability of data at wavelengths longer than 24 $\mu$m. In such cases, the IR luminosity can be estimated using only the 24 $\mu$m flux density and various SED templates (Chary & Elbaz 2001) combined with an estimated redshift. For the SMG samples, the thermal emission estimates found this way compare surprisingly well with those from stardust2 for $z \lesssim 1$ as shown in Figure 6.

\textit{Note.} $^a$ The [Ne II] emission line could be blended with the 12.7 $\mu$m PAH feature.
For these galaxies, the dominant errors on both luminosity predictors will arise from the photo-$z$ fitting; these errors are highly non-Gaussian and non-trivial to determine. To some extent, the agreement in Figure 6 can be attributed to small number statistics and selection. The overall variation in the ratio over a wider redshift range could also imply a heterogeneous SMG population. This would be consistent with the color in Figure 5 but with a varying degree of AGN contribution. Another condition on this sample is the requirement of bright optical, mid-IR, and most importantly radio identifications; at high redshift, an AGN will boost the radio flux density and the emission in other bands (notably in the mid-IR), allowing this type of analysis to be performed. However, none of the sources in the sample appear to be strongly affected by an AGN. At higher redshifts multiband analysis becomes much more difficult. Some of the higher-$z$ 850/1100 $\mu$m galaxies could simply have incorrectly identified 24 $\mu$m counterparts (see, e.g., Younger et al. 2007).

The rest-frame 12 $\mu$m flux density has been suggested to be a "pivot point" for SEDs (Spinoglio et al. 1995; see also Elbaz et al. 2002), giving a fixed $L_{12}/L_{\text{FIR}}$ for both starbursts and AGNs. This correlation was determined from local IRAS sources, but at $z \sim 1$, the rest frame 12 $\mu$m is shifted into the 24 $\mu$m band, and thus the relation at this redshift can be examined directly by our sample. We expect this relation to hold if the populations are similar. An observed difference in the populations is that distant mid-IR sources show stronger dust grain emission features around 12 $\mu$m compared to the local IR-luminous galaxy population. This difference could be due to differing AGN fractions (Wu et al. 2009).

Figure 7 shows the ratio of far-IR luminosity to observed $Spitzer$/MIPS 24 $\mu$m monochromatic luminosity as a function of redshift. The ratio flattens out at $z \sim 1$ as the rest-frame 12 $\mu$m emission is shifted into the MIPS 24 $\mu$m band, but the dispersion increases at higher redshift. This suggests that the local empirical far-IR/12 $\mu$m relation could apply to earlier epochs where the galaxy is undergoing rapid evolution, making rest-frame 12 $\mu$m flux densities a better tracer of IR luminosity (Spinoglio et al. 1995) than other mid-IR emission features, e.g., 7.7 $\mu$m PAH selected at $z \sim 2$. At $z \sim 1.4$, the silicate absorption feature is redshifted into the MIPS 24 $\mu$m band and affects the flux density measurement. This effect is emphasized in Figure 5, where an excess in the 350/24 $\mu$m colors is evident in the model SEDs, and galaxies in the redshift range where the silicate feature would cause a deficit in the 24 $\mu$m flux ($1.3 < z < 1.6$) are notably absent from Figure 7.

Various studies have suggested that the far-IR luminosity can be deduced solely from mid-IR observations of galaxies. Bavouzet et al. (2008) have shown that the far-IR luminosity of dusty galaxies observed with $Spitzer$ correlate closely with the corresponding 8 and 24 $\mu$m mid-IR luminosities. These studies were limited to redshifts $z \lesssim 1$ by the necessity to use $Spitzer$ bands at 70 and 160 $\mu$m to calculate the far-IR luminosity. The mid-IR to far-IR luminosity relation was tentatively extended to higher redshifts ($z \sim 2$) by stacking the far-infrared fluxes in the long-wavelength $Spitzer$ bands, and these stacked results were used by Caputi et al. (2007) to calculate the bolometric luminosity function at $z \sim 2$. In contrast, our submillimeter observations directly access the high-redshift universe without the need for stacking images to obtain far-infrared fluxes. From Figure 7, we observe a tight correlation between the far- and mid-IR flux densities in our sample between $1 < z < 2$, but there is a large dispersion in the infrared colors at $z > 2$. For $z \sim 2$, the 24 $\mu$m band is sampling rest wavelengths shorter than 8 $\mu$m, and the far-IR luminosity cannot be accurately predicted from such observations. In order to confirm the mid-IR/far-IR relation for $1 < z < 2$ and to test the relation to higher redshifts, large samples of SMGs will be required. Such samples will be

---

**Figure 6.** Ratio of best-fitting IR (8–1000 $\mu$m) luminosities obtained from the CE and STARDUST2 fitting, as a function of redshift. The diamonds denote the 350 $\mu$m selected galaxies, and filled circles denote the 850 and 1100 $\mu$m selected galaxies. The diamond with an arrow denotes an upper limit. Sources with redshifts beyond the usable range for the CE model ($\sim 3$) are excluded from consideration.

**Figure 7.** Ratio of far-IR luminosity to monochromatic luminosity at observed wavelength of 24 $\mu$m as a function of redshift. Data are shown for the 350, 850, and 1100 $\mu$m selected SMGs. Numerator of the ratio is the rest-frame far-IR (8–1000 $\mu$m) luminosity derived from the STARDUST2 template fitting. The denominator is the rest-frame luminosity for the 24 $\mu$m observation, i.e., monochromatic luminosity, $L_{24}^r$, at rest-frame wavelength 24 $\mu$m/(1 + $z$). At $z \sim 1$, observed 24 $\mu$m corresponds to rest 12 $\mu$m, which as Spinoglio et al. (1995) suggested gives a good measure of total luminosity. The shaded region on the plot shows the Spinoglio et al. data for local luminous infrared galaxies as they would appear at $z = 1$. Filled triangles denote sources with spectroscopic redshift, while filled circles denote sources with photometric redshifts from the STARDUST2 template fit.
available following the large surveys planned with Herschel SPIRE (at 250, 350, and 500 μm; Griffin et al. 2008).

5. CONCLUSION

The discovery of the first 350 μm selected galaxies using SHARC II offers a different insight into IR-luminous galaxies than those selected in either the mid-IR or in longer submillimeter bands. The present sample comprises IR-luminous galaxies at 1 < z < 3 and resolves ~20% of the 350 μm background at S ≥ 17 mJy. The implied lower limit on the SFRD suggests that the bulk of the 350 μm contribution is from galaxies of lower IR luminosity than the ones detected at present flux densities.

The combination of 350 μm and mid-IR flux densities allows us to examine the relation of the mid- and far-IR emission in dusty galaxies at high redshift. There is surprisingly good agreement at z < 2, with the flattening of the IR:24 μm/(1+z) luminosity ratio at z ~ 1 evidence for the local empirical relation of rest-frame 12 μm IR luminosity tracing IR luminosity applying to distant IR-luminous galaxies. The wider dispersion at z > 2 suggests a limit to which the mid-IR can be used as a proxy for far-IR emission. We also find, by comparing our 350 μm selected sample to samples chosen at 850 μm and millimeter wavelengths, no evidence for a cold color temperature bias in SMGs. These results will be further tested through surveys with Herschel-SPIRE, which will detect SMGs in unprecedented numbers.

The present 350 μm selected sample, with 15 < S_{350} < 40 mJy, is near the SPIRE 350 μm blank-field detection limit (e.g., Pearson & Khan 2009; Franceschini et al. 2009) and also the detection limits of current longer-wavelength submillimeter instruments. Counterpart identification is difficult even with the available angular resolution and will be far more difficult for space-based surveys with smaller telescopes. The achievable sensitivity and resolution of ground-based detectors will therefore provide a necessary complement to the space-based surveys, especially in characterizing the nature of the faint SMG population. Whether the first 350 μm selected galaxies typical of the population will be probed through the combination of surveys with SPIRE and future surveys from the ground (e.g., SCUBA 2–450 μm; Holland et al. 2006).

We thank Tom Phillips and the CSO for observing time and assistance during our runs, and Darren Dowell, Colin Borys, Attila Kovacs, Rick Arendt, Dave Chuss, and Bob Silverberg for providing observing and data reduction support. We thank Glenn Laurent and Kristen Coppin for advice on their 350 μm Lockman Hole follow-up surveys, Mark Brodwin and Yen-Ting Lin for assistance in compiling the Boëtes optical and near-IR photometry, and Rob Ivison for providing the radio maps for the Lockman Hole sources.

The Caltech Submillimeter Observatory is supported by NSF contract AST-0229008. This work is based in part on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA. This work is based in part on data collected at Subaru Telescope, which is operated by the National Astronomical Observatory of Japan. The Subaru data are those used by Dye et al. (2008). This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France. This research draws upon data provided by Buell Jannuzi & Arjun Dey and by Richard Elston & Anthony Gonzalez (Elston et al. 2006) as distributed by the NOAO Science Archive. NOAO is operated by the Association of Universities for Research in Astronomy (AURA), Inc., under a cooperative agreement with the National Science Foundation. The UKIDSS project is defined by Lawrence et al. (2007). UKIDSS uses the UKIRT Wide Field Camera (WFCam; Casali et al. 2007). We used data from the fourth data release (DR4).

S.A.K. is partially supported through Fondecyt Proyecto 1070992 and ALMA-Conicyt. Support for E.L.F.’s work was provided by NASA through the Spitzer Space Telescope Fellowship Program.

Facilities: CSO, Spitzer, UKIRT, Subaru, VLA, IRAM/MAMBO
