(Received 27 October 2010; accepted 15 June 2011; published online 21 July 2011)

Highly stratified shear layers are rendered unstable even at high stratifications by Holmboe instabilities when the density stratification is concentrated in a small region of the shear layer. These instabilities may cause mixing in highly stratified environments. However, these instabilities occur in limited bands in the parameter space. We perform Generalized Stability analysis of the two dimensional perturbation dynamics of an inviscid Boussinesq stratified shear layer and show that Holmboe instabilities at high Richardson numbers can be excited by their adjoints at amplitudes that are orders of magnitude larger than by introducing initially the unstable mode itself. We also determine the optimal growth that is obtained for parameters for which there is no instability. We find that there is potential for large transient growth regardless of whether the background flow is exponentially stable or not and that the characteristic structure of the Holmboe instability asymptotically emerges as a persistent quasi-mode for parameter values for which the flow is stable.

I. INTRODUCTION

The mixing of shear layers and the development of turbulence is severely impeded when the layer is located in regions of large stable stratification. The stratification is usually quantified with the non-dimensional Richardson number defined as the ratio of the local Brunt-Väisälä frequency $N$ to the square of the local shear $U$, $\text{Ri} = N^2 / U^2$. Large stratification corresponds to large Richardson numbers. The significance of the Richardson number for the stability of stratified flows has been underscored with a theorem due to Miles and Howard\textsuperscript{1,2} which proves that if everywhere in the flow $\text{Ri} > 1/4$, the flow is necessarily stable to exponential instability. The essential instability that leads primarily to mixing in both stratified and unstratified shear layers is the Kelvin-Helmholtz (KH) instability.\textsuperscript{3} The KH modes are eventually stabilized when the local Richardson number exceeds $1/4$, but if the stratification is concentrated in narrow regions within the shear layer the Richardson number may locally become smaller than $1/4$ and an instability can result although the overall stratification is very large. Under such conditions, a new branch of instability of stratified shear layers emerges as shown by Holmboe,\textsuperscript{4} consisting of a pair of propagating waves with respect to the center flow, one prograde and one retrograde. This new instability branch has been named the Holmboe (H) instability and it is physically very interesting because it persists at all stratifications and can lead to mixing in highly stratified shear layers.

Holmboe instabilities have been reproduced in laboratory experiments\textsuperscript{5–11} and have been numerically simulated.\textsuperscript{12–20} At finite amplitude, these Holmboe modes equilibrate into propagating waves and they can induce mixing in highly stratified environments.\textsuperscript{12,17,21} Consequently, Holmboe instabilities present the intriguing possibility that they may be responsible for transition to turbulence and mixing in highly stratified flows. In that vein, Alexakis\textsuperscript{18,22,23} has proposed that the surmised necessary mixing in order for a thermonuclear runway to occur and highly stratified white dwarfs form supernova explosions could be effected with Holmboe instabilities.

Holmboe\textsuperscript{4} also introduced a new method for analyzing the perplexing instabilities that may arise with the introduction of stratification. He went beyond classical modal analysis and proposed that a fruitful program for predicting and obtaining a clear physical idea of the instability of stratified shear flows is to simplify the background flow to segments of piecewise constant vorticity, as in Rayleigh’s seminal work,\textsuperscript{24} and then consider the dynamics of the edge waves that are supported at each vorticity and density discontinuity. Holmboe showed that the flow becomes unstable when the edge waves propagate with the same phase speed. This method of analysis has been extended and used to clarify the detailed mechanism of instability in stratified flows\textsuperscript{25–29} and has been shown recently by Carpenter \textit{et al.}\textsuperscript{30} to be capable of readily assessing the character of instability of non-idealized observed flows. Also, this edge wave description has elucidated the dynamics of other instabilities that occur in geophysics\textsuperscript{31–34} and astrophysics.\textsuperscript{35–37}

However, the efficacy of Holmboe modes to mix highly stratified layers can be questioned because the instability occurs only in limited regions of parameter space and the modal growth rate of the instability becomes exponentially small with stratification. Specific estimates of the asymptotic behavior of the growth rates and of the unstable band of wavenumbers has been recently obtained by Alexakis.\textsuperscript{23} Also the introduction of viscosity can further reduce the growth rates of the Holmboe instabilities. It is the purpose of this work to go beyond the modal analysis and investigate the non-modal stability of stratified shear layers that are Holmboe unstable in order to assess the true potential of growth of stratified shear layers. We will achieve this using the standard methods of generalized stability theory.\textsuperscript{38,39}

Because shear layers are powerful transient amplifiers of perturbation energy, we expect that the Holmboe instabilities...
can be excited at enhanced amplitude by composite non-modal perturbations. Even in the case of an infinite constant shear flow which has a continuous spectrum with no inviscid analytic modes and all perturbations eventually decay algebraically with time, the non-modal solutions constructed by Kelvin demonstrate that the asymptotic limit is non-uniform and perturbation energy can transiently exceed any chosen bound in the inviscid limit; the same is true for bounded Couette flow as shown by Orr. The Kelvin-Orr solutions can be extended to stratified flows and these solutions can produce transient perturbation growth that can also exceed in the inviscid limit any bound. Specifically, it can be shown that in constant shear flow and large Richardson numbers, the perturbation energy amplification is the square root of that achieved in the absence of stratification. The same robust growth resulting from the continuous spectrum is expected to persist in all shear layers as the dynamics of the Orr waves are universal and do not depend on the details of the background shear flow.

Furthermore in shear layers of finite size, the vorticity and density edge waves that are concentrated in regions of vorticity and density discontinuities can interact and produce transient perturbation growth. Also, the transiently growing Kelvin-Orr vorticity structures may deposit their energy to the edge waves to or to propagating gravity waves. In general, the continuous spectrum can excite at high amplitude the unstable or even stable analytic modes and maintain under continuous excitation high levels of variance in stable flows.

In this work, we will consider the generalized stability of a Boussinesq stratified shear layer. The Boussinesq approximation makes inaccurate predictions of the dispersion relation of the perturbations in the shear layers when the stratification is locally very large. However, we have found that the resulting optimal growths are not sensitive to this approximation, and in this paper, in order to make contact with previous work, we will only present results obtained using the Boussinesq approximation. Also following Hazel and Peltier, we will consider a continuous version of Holmboe’s velocity profile with the characteristic density stratification embedded in the shear layer. Hazel and Smyth and Peltier had analyzed the character of the bifurcations that occur in the instability of the continuous profile as the Richardson number at the center of the shear layer increases. Alexakis extended the analysis to even higher stratifications and was able to predict theoretically and show numerically that there are higher branches of Holmboe instabilities in these continuous profiles. Because of the geophysical and astrophysical interest, we will concentrate our analysis of non-modal perturbation growth of shear layers at very high Richardson numbers which possess sparse islands of exponential instability of low growth rate.

II. FORMULATION

We will study the stability of an inviscid, unidirectional, stratified, step like channel flow to two dimensional incompressible perturbations. The mean flow is characterized by a velocity jump $\Delta U$ over a vertical scale $h_0$, and the associated stably mean density is characterized by a density jump $\Delta \rho$. The linearized nondimensional perturbation equations about the mean flow $U_0(z)$ and mean density $\rho_0(z)$ in the Boussinesq approximation are

\[
(\partial_t + U_0 \partial_z)u = -U_0 w - \partial_z p, \tag{1a}
\]
\[
(\partial_t + U_0 \partial_z)w = -J \rho - \partial_z p, \tag{1b}
\]
\[
(\partial_t + U_0 \partial_z)\rho = -\rho_0 w, \tag{1c}
\]
\[
\partial_z u + \partial_z w = 0. \tag{1d}
\]

The density of the fluid has been decomposed as $\rho = \rho_m + \rho_0(z) + \varphi(x,z,t)$, where $\rho_m$ is the mean background density, $\rho_0(z)$ is the mean density variation, and $\varphi(x,z,t)$ is the perturbation density, and furthermore, according to the Boussinesq approximation, we assume, $|\rho_0| \ll \rho_m$ and $|\varphi| \ll \rho_m$. We denote with $u$ and $w$, the perturbation velocities in the streamwise ($x$) and vertical ($z$) direction, and $p$ is the perturbation reduced pressure. Differentiation with respect to $z$ is denoted with a dash. The perturbation equations have been made nondimensional, choosing $h_0$ as the length scale, $\Delta U$ as the velocity scale, and $\Delta \rho$ as the scale for the density. Time has been scaled with $h_0/\Delta U$, and pressure has been scaled with $\rho_m(\Delta U)^2$. The local Richardson number is

\[
\text{Ri} = -J \frac{\rho_0}{U_0^2}, \tag{2}
\]

with

\[
J = \frac{g \Delta \rho h_0}{\rho_m \Delta U^2}. \tag{3}
\]

$J$ provides a measure of the bulk Richardson number of the shear layer. We will assume that the flow is in a channel of length $L = 2h_0$ and impose at the channel boundaries zero vertical velocity, $w$, and zero perturbation density, $\varphi$. The length of the channel has been selected so that boundaries do not affect in an important way the results that we report in this paper. We have checked by doubling the channel size that the eigenspectrum and the perturbation transient growth are converged. Similar insensitivity to the location of the channel walls has been previously reported by Alexakis.

The perturbation equations can be written compactly by introducing a streamfunction $\psi$ so that the velocities are $u = \partial_z \psi$ and $w = -\partial_x \psi$, and the vertical displacement, defined through the relation:

\[
(\partial_t + U_0 \partial_z)\eta = w, \tag{4}
\]

can replace the perturbation density as

\[
\varphi = -\rho_0 \eta. \tag{5}
\]

The perturbation state will be determined by the fields $\psi$ and $\eta$. Because of homogeneity in the streamwise direction, the perturbation state can be decomposed in Fourier components in $x$

\[
\hat{\mathbf{x}}(z,t) = [\hat{\psi}(z,t), \hat{\eta}(z,t)]^T e^{jx} \tag{6}
\]
and the perturbation dynamics for the Fourier amplitudes for each wavenumber \( k \) can be written compactly in the form:

\[
\frac{\partial \hat{x}}{\partial t} = \mathbb{A} \hat{x},
\]

with the operator \( \mathbb{A} \) given by

\[
\mathbb{A} = -i k \left[ \Delta^{-1} \left( U_0 \mathbb{A} - U_0^\prime \right) \frac{J \Delta^{-1} \rho_0^\prime}{U_0} \right].
\]

With \( \Delta = \frac{\partial^2}{\partial z^2} - k^2 \), we denote the two dimensional Laplacian for the \( k \) streamwise wavenumber. \( \Delta^{-1} \) is the inverse Laplacian, the inversion being rendered possible and unique by imposing the boundary conditions on the upper and lower boundaries. The perturbation Eq. (7) is equivalent to the time dependent Taylor-Goldstein equation:

\[
(\partial_t + i k U_0) \Delta \hat{\psi} - i k U_0^\prime (\partial_z + i k U_0) \hat{\psi} + k^2 J \rho_0^\prime \hat{\psi} = 0.
\]

### III. KELVIN-HELMHOLTZ AND HOLMBOE INSTABILITIES OF A SHEAR LAYER

Following Hazel,\(^{55}\) we consider the following background mean velocity and density

\[
U_0(z) = \frac{1}{2} \tanh(2z), \quad \rho_0(z) = -\frac{1}{2} \tanh(2Rz).
\]

The mean velocity and density profiles are shown in Fig. 1 for \( R = 3 \). The parameter \( R \) is the ratio of the width of the shear layer to the width of the region over which the density jump occurs. The local Richardson number is given by

\[
\mathrm{Ri}(z) = RJ \frac{\text{sech}^2(2Rz)}{\text{sech}^2(2z)}.
\]

The Richardson number at the center is related to the bulk Richardson number through the relation:

\[
\mathrm{Ri}(0) = RJ.
\]

When \( R = 1 \), the local Richardson number assumes its minimum value at the center, \( \mathrm{Ri}(0) = RJ \), and the shear layer is unstable only if \( \mathrm{Ri}(0) < 1/4 \). The instability that results is a Kelvin-Helmholtz (KH) type instability with a short wave cutoff and zero phase velocity. For \( R > 2 \), the Richardson number decays exponentially to zero. This exponential decay allows the local Richardson number to be in regions smaller than 1/4, and the shear layer may become unstable although both the bulk stratification \( J \) and \( \mathrm{Ri}(0) \) may be very large. The instabilities that occur under these conditions are the Holmboe instabilities (H). The variation of the Richardson number with height is shown in Fig. 2 for \( R = 3 \), a case that supports Holmboe instabilities and will be treated in detail in this paper, and for \( R = \sqrt{2} \) which can support only KH instability when the Richardson number at the center is smaller than 1/4.

In order to determine the modal stability of the velocity and density profiles (10), we assume modal solutions of Eq. (7) of the form \( \hat{x}(z,t) = [\psi(z), \tilde{\eta}_z(z)]^T e^{-i c_t z} \), with \( -i c_t \) an eigenvalue of the evolution operator \( \mathbb{A} \) in Eq. (8). The modal growth rate of the perturbation is \( k c_i \) where \( c_i = \Re(c) \), and the flow is exponentially unstable to perturbations of wavenumber \( k \) if \( c_i > 0 \). The real part, \( c_r \), of the eigenvalue \( c(k) \), gives the phase speed of the perturbation. Detailed analysis of the eigenspectrum of Eq. (10) and the bifurcation from KH instabilities to H instabilities has been already performed.\(^{18,22,55-57}\) Here, we review the basic stability characteristics for the case of \( R = 3 \) that admits both KH and H instability modes.

The transition from KH instability to H instability is shown in Fig. 3, where we plot the growth rate and phase speed as a function of the Richardson number at the center of the shear zone \( \mathrm{Ri}(0) \) for \( k = 0.3 \). For \( \mathrm{Ri}(0) < 0.242 \), there is a single unstable Kelvin-Helmholtz instability with phase speed \( c_r = 0 \). At \( \mathrm{Ri}(0) = 0.242 \), a second KH mode becomes unstable, also with \( c_r = 0 \). The KH modes coalesce at \( \mathrm{Ri}(0) = 0.258 \) to form a propagating pair of unstable Holmboe modes with equal and opposite phase speeds and the same growth rate. In this case, we see two branches of KH instabilities existing.
even when the center Richardson number exceeds 1/4 (the Richardson number assumes values smaller than 1/4 away from the center because the parameter is $R = 3$, see Fig. 2); a similar case can be found in Smyth and Peltier.\cite{Smyth56}

Numerical results were obtained by discretizing the channel and all differential operators using second order centered differences and incorporating the appropriate boundary conditions. Equation (7) then becomes a matrix equation in which the state becomes a column vector. We used a staggered grid, that is, we evaluated $\psi_r(z)$ at $N$ interior points in the vertical and $\eta_r(z)$ at $N + 1$ points located halfway between the collocation points of the streamfunction. The eigenspectrum is obtained by eigenanalysis of operator $\Lambda$. Calculations, unless otherwise specified, were performed with $N = 1001$ in the domain $-2 \leq z \leq 2$. With this discretization, the finite time evolution of the dynamics is well resolved when there is no instability up to a time of $t = O(1/|z_0k\Delta z|)$, where $z$ is the typical shear.\cite{Constantinou10} However, in order to numerically resolve the curves of zero modal growth of the Holmboe modes of instability, we had to include numerical diffusion in both the momentum and density equations with coefficient of diffusion $\nu = (\Delta z/2)^2$ in the momentum equation and $\nu/9$ in the density equation for the case $R = 3$ ($\Delta z$ is the grid spacing). Very accurate determination of the neutral curve in the inviscid limit can be obtained, using the shooting method as in Alexakis.\cite{Alexakis23}

Growth rate contours as a function of stratification, $J$ or $\text{Ri}(0)$, and wavenumber, $k$ are shown in Fig. 4 for $R = 3$. The region of $\text{KH}$ instability is concentrated for small Richardson numbers, and it is not discernible in this plot. However, the bands of instability corresponding to the various Holmboe modes of instability can be clearly seen. Note that because of the inclusion of diffusion, the instability bands do not extend to infinity as they do in the inviscid limit.\cite{Constantinou10, Alexakis23, Smyth56}

FIG. 3. (Color online) Bifurcation properties of the unstable modes as a function of the Richardson number at the center of the shear zone $\text{Ri}(0) = RJ$ for the mean state given by Eq. (10) for $R = 3$ and perturbations with $k = 0.3$. (a) The growth rate $k_{c1}$; (solid); (b) the associated phase speed $c_r$; (dashed-dotted). For $\text{Ri}(0) < 0.242$, there is a single Kelvin-Helmholtz (KH) mode with zero phase speed. For $0.242 < \text{Ri}(0) < 0.258$, there are two KH modes with zero phase speed. The two KH modes coalesce to produce two unstable Holmboe (H) modes with equal and opposite phase speeds.

FIG. 4. (Color online) Contours of modal growth rate $k_{c1}$ of the perturbation operator $\hat{\Lambda}$ as a function of wavenumber, $k$, and the bulk Richardson number, $J$, for $R = 3$. Because of the inclusion of diffusion the instability bands do not extend to infinity as do in the inviscid limit. The corresponding value of the Richardson number at the origin $\text{Ri}(0) = RJ$ is also recorded at the ordinate axis on the right. For this value of $R$, there are KH unstable modes with phase speed $c_r = 0$ for small values of $J$ (barely discernible in this plot) and three unstable bands of pairs of H instabilities with prograde and retrograde phase speeds for higher $J$.\cite{Alexakis23}

FIG. 5. (Color online) Growth rates $k_{c1}$ as a function of wavenumber $k$ for $R = 3$ and center Richardson numbers $\text{Ri}(0) = 0.06, 0.65, 12$ for which we have, respectively, KH mode instability, $H1$ and $H2$ instabilities.

Typical structure of the KH instability mode is shown in Fig. 6 for $k = 1$, $R = 3$, and $\text{Ri}(0) = 0.06$. For these parameters, the coalescence of the KH modes and the emergence of the first Holmboe mode of instability occurs at $\text{Ri}(0) = 0.182$. The Holmboe modes come in prograde and

FIG. 6. (Color online) Typical structure of the KH instability mode is shown in Fig. 6 for $k = 1$, $R = 3$, and $\text{Ri}(0) = 0.06$. For these parameters, the coalescence of the KH modes and the emergence of the first Holmboe mode of instability occurs at $\text{Ri}(0) = 0.182$. The Holmboe modes come in prograde and...
retrograde pairs. The prograde and retrograde unstable Holmboe modes, H1, for \( R_i(0) = 0.65 \) are shown in Fig. 7. Because they are symmetric with respect to \( z = 0 \), we will subsequently plot only the prograde branch of the H mode. Higher Holmboe modes have larger vertical wavenumbers, the case of H2 is shown in Fig. 8. In the idealized piecewise constant problem studied by Holmboe (see Appendix) the prograde Holmboe instability arises from resonant interaction between the edge waves at the density discontinuity at the center with the edge wave at the upper vorticity discontinuity for the prograde instability, and with the edge wave at the lower vorticity discontinuity for the retrograde instability. The same type of interaction gives rise to the Holmboe instability modes when the discontinuities of the background are smoothed as for the background given by Eq. (10). Because of the delta function nature of the vorticity and stratification gradient, the edge waves in Holmboe’s idealized profile do not have internal structure, and as a result, there is a single pair of unstable Holmboe instabilities that can arise from the interaction. The smoothed profile allows the edge wave to obtain vertical structure within the regions of large vorticity and stratification gradient (cf., respectively, to the left and right panels of Figs. 7 and 8) and the H2, H3, etc. Holmboe instabilities emerge with the higher modes associated with higher vertical wavenumber structure.

IV. OPTIMAL EXCITATION OF KELVIN-HELMHOLTZ AND HOLMBOE MODES

The perturbation dynamics in a stratified shear flow are non-normal and, as we will show in this section, the unstable modes emerge through excitation of their adjoint. In order to determine the growth that results by introducing initially the adjoint of the unstable mode, we derive the adjoint perturbation dynamics in the energy norm. For a perturbation of wavenumber \( k \), the total average kinetic energy over a wavelength in the region \( [z_1, z_2] \) is

\[
T = \frac{1}{4} \int_{z_1}^{z_2} d\hat{x} \cdot (-\Delta \hat{x}),
\]

and the potential energy is:

\[
V = \frac{1}{4} \int_{z_1}^{z_2} dz \left( -\rho_0 \right) \hat{\eta} \hat{\eta}.
\]

The total energy of a perturbation \( \hat{x} = [\hat{\psi}, \hat{\eta}]^T \) is thus given by the inner product:

\[
\|\hat{x}\|^2 = \langle \hat{x}, \hat{x} \rangle = \frac{1}{4} \int_{z_1}^{z_2} d\hat{x} \cdot \left[ (-\Delta \hat{\psi}) + J(-\rho_0) \hat{\eta} \hat{\eta} \right].
\]
The adjoint operator $A^\dagger$ in this inner product is defined as the operator that satisfies

$$
\left( A^\dagger \tilde{f}, \tilde{g} \right) = \left( \tilde{f}, A \tilde{g} \right),
$$

(16)

for any two states $\tilde{f} = [\tilde{\psi}_x, \tilde{\eta}_x]^T$ and $\tilde{g} = [\tilde{\psi}_x, \tilde{\eta}_x]^T$. For a discussion of the adjoint equation in fluid mechanics, see Farrell, Hill, Farrell and Ioannou, Chomaz et al., and Schmid and Henningson.

From Eq. (16), the adjoint operator of Eq. (8) in the energy inner product is easily shown to be

$$
A^\dagger = ik \left[ \Delta^{-1} (U_0 \Delta + 2U_0' D) \right] \frac{1}{U_0},
$$

(17)

with $D = d/dz$ denoting differentiation with respect to $z$ and the adjoint evolution equation is

$$
\frac{\partial \tilde{x}_x}{\partial t} = A^\dagger \tilde{x}_x
$$

(18)

with the adjoint boundary conditions $\tilde{x}_x(z_i, t) = 0$ at the channel walls $z_i$. This equation produces the adjoint of the time-dependent Taylor-Goldstein Equation (9)

$$
(\partial_t - ikU_0)^2 \Delta \tilde{\psi}_x - 2ikU_0 (\partial_t - ikU_0) D \tilde{\psi}_x - k^2 \rho'_0 \tilde{\psi}_x = 0.
$$

(19)

The eigenvalues of the adjoint operator $A^\dagger$ are the complex conjugate of the eigenvalues of $A$, and in this way, we can establish a correspondence between the modes of the adjoint $A^\dagger$ and the modes of $A$. Further, the mode of the adjoint with eigenvalue $-ikc^*$, $\tilde{x}_{xc}$, and the mode of $A$ with eigenvalue $-ikc'$, $x_c$, satisfy the biorthogonality relation:

$$
(\tilde{x}_{xc}, \tilde{x}_c) = 0 \quad \text{for} \quad c \neq c'.
$$

(20)

From Eq. (19), it can be verified that for any analytic mode of the Taylor-Goldstein Equation (9) with eigenvalue $-ikc$ (with $c > 0$ or with $c_i$ outside the range of the background flow) the mode of $A^\dagger$ with eigenvalue $ikc^*$ is

FIG. 9. (Color online) Structure of the streamfunction (panel (a)) and density (panel (b)) perturbation fields of the adjoint of the unstable KH mode of Fig. 6. Parameters as in Fig. 6.

FIG. 10. (Color online) Structure of the streamfunction and density perturbation fields of the adjoint of the unstable prograde H1 mode of Fig. 7. The adjoint is centered at the critical layer, $z_i = 0.264$, of the mode.

FIG. 11. (Color online) Structure of the streamfunction and density perturbation fields of the adjoint of the unstable prograde H2 mode of Fig. 8. The adjoint is centered at the critical layer, $z_i = 0.698$, of the mode.
and the maximum projection on a given mode is achieved by the adjoint mode, i.e., by choosing $x = x_a$. The adjoint perturbation excites the mode at an energy which is a factor greater than an initial condition consisting of the mode itself. For highly non-normal systems, $|\langle x_a, x \rangle| < \lambda_1$, and as a result this amplification may be very large, implying that the emergence of the mode in these systems is mainly due to the excitation of the adjoint. Although this is not a new result, it has not been noted in previous studies concerning Holmboe instabilities.

In Fig. 9, we plot the structure of the adjoint in the energy inner product of the unstable KH mode shown in Fig. 6 with $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 9, we plot the structure of the adjoint in the energy inner product of the unstable KH mode shown in Fig. 6 with $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 10, we plot the structure of the adjoint in the energy inner product of the unstable H1 mode shown in Fig. 10 and the H2 mode shown in Fig. 11 are introduced at $t = 0$ (solid); also shown is the energy evolution if the H1 mode and H2 mode are introduced at $t = 0$ (dashed). The adjoint excites the corresponding modes optimally. The adjoint of the H1 mode excites the mode with energy 69 times greater than an initial condition consisting of the H1 mode itself. The H2 adjoint excites the mode with energy 7921 times greater than an initial condition consisting of the H2 mode itself. Parameters are $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 11, we plot the structure of the adjoint in the energy inner product of the unstable H2 mode shown in Fig. 11. The adjoint of the H2 mode excites the mode with energy 7921 times greater than an initial condition consisting of the H2 mode itself. Parameters are $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 12, we plot the structure of the adjoint in the energy inner product of the unstable KH mode shown in Fig. 6 with $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 13, we plot the structure of the adjoint in the energy inner product of the unstable H1 mode shown in Fig. 10 and the H2 mode shown in Fig. 11. The adjoint of the H1 mode excites the mode with energy 69 times greater than an initial condition consisting of the H1 mode itself. The H2 adjoint excites the mode with energy 7921 times greater than an initial condition consisting of the H2 mode itself. Parameters are $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 14, we plot the structure of the adjoint in the energy inner product of the unstable H2 mode shown in Fig. 11. The adjoint of the H2 mode excites the mode with energy 7921 times greater than an initial condition consisting of the H2 mode itself. Parameters are $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 15, we plot the structure of the adjoint in the energy inner product of the unstable KH mode shown in Fig. 6 with $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 16, we plot the structure of the adjoint in the energy inner product of the unstable H1 mode shown in Fig. 10 and the H2 mode shown in Fig. 11. The adjoint of the H1 mode excites the mode with energy 69 times greater than an initial condition consisting of the H1 mode itself. The H2 adjoint excites the mode with energy 7921 times greater than an initial condition consisting of the H2 mode itself. Parameters are $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.

In Fig. 17, we plot the structure of the adjoint in the energy inner product of the unstable H2 mode shown in Fig. 11. The adjoint of the H2 mode excites the mode with energy 7921 times greater than an initial condition consisting of the H2 mode itself. Parameters are $k = 1, R = 3$, and for the H1 mode, the stratification is $Ri(0) = 0.65$, while for the H2 mode, $Ri(0) = 12$.
Initial conditions in the form of the adjoints of the most unstable mode evolve changing form and eventually assume the corresponding modal form. During their evolution, the adjoint perturbation extracts energy from the mean flow which is eventually deposited to the mode itself exciting it in this way at high amplitude. The time development of the energy of a unit energy initial condition in the form of the adjoints of the H1 and H2 mode is plotted in Fig. 12 demonstrating the increased excitation of the corresponding modes. This demonstrates that the unstable Holmboe modes at high Richardson numbers arise primarily due to excitation by their adjoint and the modal growth underestimates the growth of the instabilities.

V. OPTIMAL GROWTH OF PERTURBATIONS AND THE EMERGENCE OF THE HOLMBOE QUASI-MODE

In the previous section, we have demonstrated that for large Richardson numbers, the adjoint of a mode can excite the modes at much higher amplitude. In this section, we investigate the optimal growth of perturbations. The optimal growth of perturbations at time $t$ in the energy metric is obtained by calculating the norm of the propagator $e^{AMt}$, where $A_M = M^{1/2}AM^{-1/2}$ and $M$ is the energy metric defined as

$$M = \frac{\Delta z}{4} \begin{bmatrix} -(D^2 - k^2) & 0 \\ 0 & -J\rho_0 \end{bmatrix},$$ (26)

FIG. 17. (Color online) Contours of the logarithm of the positive real part of the perturbation $\Re(\psi(z,t)e^{i\omega t})$ at $z = 0.7$ in the $(x, t)$ plane for an initial perturbation in the form of the adjoint in the energy norm of the most unstable Holmboe mode at $k = 3.5$ for $R = 3$ and $Ri(0) = 5$. Panel (a): evolution under the dynamics with $k = 1.75$ when the flow is stable. Panel (b): evolution under the dynamics with $k = 3.5$ when the flow is unstable and this adjoint excites optimally the prograde Holmboe mode. The same propagation characteristics emerge at other wavenumbers for which the flow is stable. These Hovmöller diagrams indicate that when the flow is stable, a quasi-mode emerges propagating with phase speed close to that of the Holmboe mode.
so that total perturbation energy is given by $E = \frac{1}{2}\mathbf{x}^\dagger M\mathbf{x}$. The optimal growth is given by the largest singular value, $\sigma_{\text{max}}$, of $e^{\lambda k t}$ and determines the largest perturbation growth that can be achieved at time $t$. The optimal perturbation, the initial perturbation that produces this growth, is $\mathbf{x}_{\text{opt}} = M^{-1/2}\mathbf{v}$, where $\mathbf{v}$ the right singular vector with singular value $\sigma_{\text{max}}$.

We calculate the optimal growth for two indicative optimizing times $t = 100$ and $t = 600$ and plot the finite time Lyapunov exponent $\ln(\sigma_{\text{max}}(t))/t$ associated with the optimal perturbations as a function of wavenumber $k$ and stratification $J$. As $t \to \infty$, the exponent tends to the modal growth rate $\ln(\sigma_{\text{max}})/t \to kc_r$. We saw that the modal growth rate (cf. Fig. 4) is non zero only in narrow bands of parameter space. In contrast, the growth rate associated with the optimal perturbations covers all parameter space. For example, for optimizing time $t = 100$, the finite Lyapunov exponent, shown in Fig. 13, is almost constant for large Richardson numbers, and the equivalent growth rates for large Richardson numbers are at least an order of magnitude larger than the modal growth rates for all values of the parameters. Furthermore, the growth rates do not reveal the underlying bands of exponential instability. The optimal growth is robust even for optimizing time $t = 600$. Contours of the finite Lyapunov exponents for this optimizing time (Fig. 14) show that the optimal growth rates continue to be at least an order of magnitude larger than the modal growth rate for all parameter values. Moreover, the optimal growth rates are almost constant as a function of Richardson number for large Richardson numbers. This can be seen in Fig. 15, where we compare the optimal growth rate for optimizing times $t = 50$, 200, and 600 with the modal growth rate as a function of the stratification at the center $\text{Ri}(0)$ for $k = 1$. While the modal growth rate is only substantial for the H1 branch of instability, the optimal growth rates produce sustainable growth at all stratifications and are reduced only by a factor of less than 2 when the center Richardson number increases tenfold from 5 to 50.

The structure of the optimal perturbations for the larger optimizing times is very close to the structure of the adjoint of the modes, even for wavenumbers for which there is no Holmboe instability. This reveals that excitation of these flows at high Richardson numbers will lead to the emergence of propagating perturbations which are close in structure to Holmboe waves. To be specific, consider central stratification $\text{Ri}(0) = 5$ and excitation of the shear layer with various wavenumbers $k$. In Fig. 16, we plot the growth rate as a function of $k$. There is a band of instability producing H1 waves with phase speeds close to $c_r \approx \pm 0.5$ and when the flow is excited at these wavenumbers pairs of propagating waves emerge. This can be seen in the Hovmöller diagram Fig. 17(b) in which contours of the logarithm of the positive real part of $R(\tilde{y}(z, t)e^{\beta z})$ for $k = 3.5$ and fixed $z = 0.7$ are plotted in the $(x, t)$ plane for an initial condition in the form of the adjoint of the unstable H1 mode. The characteristics of the prograde propagating Holmboe wave emerge from the start. In Fig. 17(a), we plot the corresponding Hovmöller diagram when the same adjoint is introduced as initial condition and evolved this time with the dynamics for $k = 1.75$. Although at $k = 1.75$, there is no instability, a propagating structure emerges with the characteristics of the unstable Holmboe wave. The same propagating structure also emerges at other wavenumbers $k$. Therefore, the Holmboe wave is a robust dynamic entity that forms a quasi-mode at wavenumbers which do not support an unstable Holmboe wave. This quasi-mode is the manifestation of the near resonant edge wave structures that lead to the Holmboe instability at resonance $4.25–28,30$. Similar quasi-mode behavior is seen in the evolution of the edge waves in the Holmboe profile (cf. Appendix) for wavenumbers $k$ for which there is no instability. When $k$ is close to the wavenumber for which there is instability there exist superpositions of edge waves that form periodically amplifying quasi-modes that propagate with a phase speed which is close to the phase speed of the unstable Holmboe mode. What is surprising here is that these propagating quasi-modes can be excited at such high amplitude and that their growth is so persistent. This is shown in Fig. 18 where the adjoint of the Homboe instability for $k = 3.5$ excites at high amplitude quasi-modes for the wavenumbers $k = 1, 2, 2.5, 4$ for which the flow is stable. The same highly amplified quasi-mode would emerge if we initialize the flow with a large time optimal.

The structure of the quasi-mode cannot be ascribed to the structure of any single mode of the operator. The quasi-mode is the superposition of a multitude of continuum spectrum modes. The quasi-mode can propagate as a coherent entity at a single phase speed because the distribution of the amplitude of the coefficients of the modal expansion is sharply peaked at the phase speed of the propagation of the quasi-mode (the amplitude of the coefficients is time invariant because all modes have zero growth). For example, the distribution of the amplitude of coefficients of the modal expansion of the quasi-mode for $k = 1.75$ in Fig. 19 is concentrated at the phase speed $c_r \approx \pm 0.4278$, which is exactly the phase speed that emerges in Fig. 17(a).

The quasi-mode can be identified from the frequency response of the perturbation dynamics to harmonic forcing. Because the operators are either neutral or unstable in order to

\[ \text{Fig. 20. (Color online) The maximum energy response, } \|R(\omega)\|^2, \text{ to harmonic forcing as a function of } \omega/k \text{ for perturbations with } k = 1, k = 2.5, k = 3.5, \text{ and } k = 4.0. \text{ The dynamics have been rendered stable by addition of Rayleigh friction. The response is maximized at the phase speed of the quasi-mode. Also shown is the resonant frequency response that would obtain if the operators were normal (dashed). The amplified response in energy is a measure of the non-normality of the operator. For stratification, } \text{Ri}(0) = 5 \text{ and } R = 3. \]
of the Holmboe waves at $k = 3.5$. It demonstrates also the importance of the non-normal interactions in the excitation at high amplitude of the quasi-modes. In the same plot, we plot the equivalent normal frequency response

$$\max_i \frac{1}{|\imath \omega - \mathbf{k} c_j|^2},$$

where $\mathbf{k} c_j$ is the $j$th eigenvalue of $\mathbf{A}_M$ that would have resulted if the eigenvectors were orthogonal. The difference between the responses reflects the excess energy that is maintained by the system against friction because of the non-orthogonality of the eigenmodes.\textsuperscript{53,62}

**VI. CONCLUSIONS**

Highly stratified shear layers are susceptible to Holmboe instabilities which can lead to mixing. We have demonstrated in this work that especially at large Richardson numbers the adjoint of the weakly unstable modes can excite, through potent transfer of energy from the mean flow, the unstable modes at high amplitude. Further, we found that even in regions of parameter space where the flow is neutral, optimal perturbations can grow strongly and excite at large amplitude long-lived propagating quasi-modes. We have demonstrated that the modal growth substantially underestimates the growth potential of perturbations in such highly stratified shear layers.

**APPENDIX: NON-MODAL GROWTH PRODUCED BY THE EDGE WAVES IN THE IDEALIZED HOLMBOE BACKGROUND STATE**

We consider perturbations in Holmboe’s\textsuperscript{4} idealized piecewise linear velocity profile $U_0(z) = z$ for $|z| \leq 1/2$ and $U_0(z) = z/(2|z|)$ for $|z| > 1/2$ and mean density $\rho_0(z) = -z/|z|$ in an infinite domain. This profile has two vorticity discontinuities at $z = \pm 1/2$ and a density discontinuity at $z = 0$; each vorticity discontinuity supports an edge wave and the density discontinuity supports a pair of edge waves one prograde and the other retrograde.\textsuperscript{4,28,29} Consider perturbations with streamfunction $\tilde{\psi}(z, t)e^{ikz}$. A time dependent solution to the perturbation equations can be obtained\textsuperscript{4,25} by introducing solutions of the form,

$$\tilde{\psi}_1(z, t) = A_1(t)e^{-k(z-1/2)} \quad \text{for } z > 1/2, \quad (A1a)$$

$$\tilde{\psi}_2(z, t) = A_2(t)e^{-kz} + B_2(t)e^{kz} \quad \text{for } 0 < z < 1/2, \quad (A1b)$$

$$\tilde{\psi}_3(z, t) = A_3(t)e^{-kz} + B_3(t)e^{kz} \quad \text{for } -1/2 < z < 0, \quad (A1c)$$

$$\tilde{\psi}_4(z, t) = B_4(t)e^{k(z+1/2)} \quad \text{for } 0 < z < 1/2, \quad (A1d)$$

which reduce them, by imposing the usual continuity conditions at the discontinuity interfaces, to a set of ordinary differential equations for the evolution of the amplitudes $A$ and $B$. 

![Image](image-url)
We choose as a state variable \( \mathbf{u}(t) = [A_1(t), C_2(t), B_2(t), \eta_0(t)]^T \), where \( \eta_0(t) \equiv \bar{\eta}(z = 0, t) \) is the displacement at \( z = 0 \) and \( C_2(t) \equiv (A_2(t) + B_2(t))e^{k/2} \). The perturbation equations are thus reduced to

\[
\frac{d\mathbf{u}}{dt} = \mathbf{A}\mathbf{u},
\]

These equations determine the time evolution of the perturbation structure as determined by the interaction of the four edge waves. It determines fully the modal stability properties and edge waves. It determines fully the modal stability properties as determined by the interaction of the four edge waves. In this formulation, we have neglected the continuum spectrum. A contour plot of the resulting growth rate is shown in Fig. 21 as a function of wavenumber, \( k \), and stratification parameter, \( J \). The KH branch of instability is at low \( k \) and \( J \) and the narrowing band of the Holmboe mode of instability at larger \( k \) and \( J \).

In order to study the non-normal dynamics associated with the edge waves we must introduce the corresponding to Eq. (15) energy metric. The potential energy, since \( \rho_0' = -\delta(z) \), is \( P = \frac{1}{2} \rho_\delta \eta_0 \). The kinetic energy can be written as

\[
T = \frac{1}{4} \left[ (1 + e^k(k - 1))/2 - k/2 \right] = 0 \quad 0 \quad (1 + e^k(k - 1))/2 - k/2 \quad 0 \quad 0 \quad (1 + e^k(k - 1))/2 - k/2 \quad 0 \quad 0 \quad (1 + e^k(k - 1))/2 - k/2 \quad 0 \quad 0 .
\]

We thus derive that the perturbation energy of the state \( \mathbf{u}(t) \) is given by

\[
E = \mathbf{u}^\dagger \mathbf{M} \mathbf{u},
\]

with the metric, \( \mathbf{M} \), given by

\[
\mathbf{M} = \frac{1}{4} \begin{bmatrix} \mathbf{M}_T & 0 \\ 0 & J \end{bmatrix}
\]

where \( \mathbf{M}_T \) is

\[
\mathbf{M}_T = \frac{2k}{(e^k - 1)} \begin{bmatrix} e^k & -1 & 0 \\ -1 & 1 + e^{-k} & -1 \\ 0 & -1 & e^k \end{bmatrix}.
\]

The non-modal growth associated by the dynamics of the edge waves is obtained by calculating the optimal energy growth that can be achieved at time \( t \) which is given by

\[
E_{opt}(t) = \| \exp(\mathbf{A}_M t) \|^2
