Bilateral discoid medial meniscus
Re-teared meniscus
Degeneration of cartilage
Meniscus allograft transplantation

A B S T R A C T
In symptomatic discoid medial meniscus, partial meniscectomy is the principal treatment method and can yield promising short-term results. However, unlike the nondiscoid meniscus, discoid medial meniscus is frequently associated with horizontal cleavage tears, attributable to the presence of myxoid degeneration in the intrameniscal substance, in that it may potentially occur deteriorating long-term results because of re-tearing of remaining meniscus or secondary degeneration of cartilage of the medial compartment after meniscectomy. We experienced three rare cases of retear or secondary degeneration of cartilage of the medial compartment after meniscectomy for two patients with torn bilateral meniscus. Both patients were highly active young males. Meniscal allograft transplantation in complicated discoid medial meniscus was performed. At 2 years after meniscal allograft transplantation, clinical outcomes were improved with a normal range of motion. Orthopedic surgeons should recommend activity modification to prevent possible complicated injury of the discoid medial meniscus. Meniscal allograft transplantation may be an alternative option in highly active young patients undergoing complicated discoid medial meniscus to diminish pain, improve knee function, and prevent or delay degeneration.

Introduction

The discoid medial meniscus is a rare anatomical variant in which the normal thin and crescent-shaped cartilage is replaced by a thickened and fuller shape that does not taper fully towards the midline. Bilateral cases are more rare, with only 20 cases of bilateral discoid medial meniscus reported. While the anomaly itself is generally asymptomatic, a combination of reduced blood supply, increased thickness and a potentially weak capsular attachment is thought to increase the risk of tearing as compared to the normal variant. This anomaly can be diagnosed at any age, but is generally diagnosed in young subjects with considerable functional and athletic demands. In symptomatic discoid medial meniscus, partial meniscectomy and peripheral side repair as necessary is typically recommended, with good short-term follow-up results. Resection of almost the entire discoid meniscus is sometimes necessary because of the complexity and extent of the tear or re-tear after partial meniscectomy. Meniscal allograft transplantation (MAT) was developed as a means of treating the symptoms of compartmental overload after total meniscectomy, with improvement in knee function at short- and midterm follow-up, as well as acceptable complication and failure rates. Here, we experienced two rare cases of bilateral discoid medial meniscus with long-term follow-up. The three involved knees represented re-tear or secondary degeneration of cartilage of the medial compartment after meniscectomy. Both patients were highly active young males, in whom MAT in complicated discoid medial meniscus was performed.

Case reports

Patient 1

In February 2008, an 18-year-old male presented with pain and locking of the left knee that had developed abruptly. He had sustained a twisting injury of his left knee joint while playing...
soccer. Physical examination revealed medial joint line tenderness and positive McMurray’s sign, with a normal range of movements. Ligamentous instability and patellofemoral symptoms were not present. No abnormality was observed on radiographs. Magnetic resonance imaging (MRI) revealed a complex tear of the incomplete discoid medial meniscus with cystic changes around the posterior horn (Fig. 1a and b). Partial meniscectomy for torn discoid medial meniscus was performed (Fig. 1c). In January 2012, he presented with pain in both knees aggravated by climbing stairs and long-distance walking as part of his role as a professional soldier. Physical examination revealed joint tenderness and medial pain in McMurray’s test in both knees. Arthroscopy of the left knee revealed complex tears of the remaining meniscus extending from its body to the posterior horn. The meniscus had a horizontal cleavage extending to the peripheral rim accompanied by fatty degeneration (Fig. 1d). Arthroscopic subtotal meniscectomy was performed for the discoid medial meniscus. MRI of the right knee revealed an incompletely torn discoid medial meniscus with cleavage tear, and cystic change from the anterior horn to posterior horn. Arthroscopic partial meniscectomy and repair of some parts of the horizontal cleavage site were performed. However, 24 months after subtotal meniscectomy on the left knee, he had difficulties in daily activities and occupation due to the persistent pain in the medial compartment of the left knee joint. A plain radiograph showed a mild narrowing and marginal osteophyte in the left-knee medial compartment (Fig. 2a). No malalignment was detected on standing orthoroentgenogram. MAT was performed using the double bone-plug technique (Fig. 2b). The size of MAT was measured by the surgeon as described by previously and then a fresh-frozen medial meniscal allograft sterilized by BioCleanse processing was provided from the Cellumed tissue bank.

Twelve months after MAT, MRI on the left knee meniscus allograft showed secure integration of the allograft with the joint capsule and good positioning in relation to the tibiofemoral joint (Fig. 3). Two years after MAT on the left knee, clinical outcome was a visual analog scale score of 2, Lysholm score of 76 and Tegner activity scale level 5, with a normal range of movement.

**Patient 2**

In April 2010, a 21-year-old male professional soldier was referred to our hospital for a 2-month history of pain and swelling in both knees. He had a history of acute injury while running and jumping. The symptoms were worsened by long-distance walking and participation in sports activities. Physical examination revealed tenderness of the medial joint line bilaterally. The left knee featured pain and a locking sensation upon full extension. MRI revealed complete discoid medial meniscus with a complex tear bilaterally (Fig. 4a and b). Furthermore, a degenerative longitudinal tear was observed extending from the body portion to the posterior horn on the peripheral side in the right knee (Fig. 4c). Subtotal meniscectomy was performed to treat the severe marginal degeneration and fatty degeneration in the right knee. Partial meniscectomy involving the flap torn meniscus was performed in the left knee. For the inner horizontal cleavage tear, the inferior surface was also removed (Fig. 4d).
In March 2013, he suffered from pain in both knees, which was aggravated by climbing stairs and long-distance walking. No abnormality was observed on radiographs. MRI of both knees revealed worn-out medial femoral condyle and tibial condyle cartilage. A second-look arthroscopy on the left knee showed that the weight-bearing portion of the medial femoral condyle was not properly covered as a result of thinning due to a degenerative tear on the superior surface of the meniscus remaining after the meniscectomy, and cartilage wear of the femoral condyle was ongoing (Fig. 5a and b). The patient had difficulties in daily activities and as a professional soldier due to the persistent pain in the medial compartment of both knee joints. MAT was performed using the bone plug technique. Thirteen months after MAT on both knees, MRI of both knees showed sound peripheral healing of the joint capsule. The cartilage wear area on the medial femoral condyle side was well covered (Fig. 6a and b). At two years, clinical outcome was measured using a visual analog scale for pain (right: 2/left: 2), Lysholm score (right: 76/left: 78) and Tegner activity scale (level 5), with a normal range of movement.

Discussion

The origin of discoid meniscus is not well understood. Defective disappearance of the meniscal center during fetal development, with persistence of the fetal stage into adulthood has been suggested. Meniscal subluxation was defined as the distance from the tibial plateau to the outer edge of the meniscus. Secure integration of the allograft with the joint capsule and good positioning in relation to the tibiofemoral joint were evident. No frank extrusion of the allograft out of the tibiofemoral joint was evident.
circumferential collagen network in the discoid meniscus in comparison with the normal meniscus. So the discoid meniscus likely represents a structural lesion rather than a morphological variant and supports the argument that the discoid meniscus is susceptible to higher rates of tear and degeneration compared with meniscus of normal configuration. Discoid medial meniscus is generally diagnosed with tear and degeneration in young subjects with considerable functional and athletic demands. In both cases presented herein, bilateral discoid medial meniscus was diagnosed in highly active young males. Complex tear associated horizontal cleavage tear with meniscal cyst and degeneration were detected. Although treatment for discoid medial meniscus depends on the morphometrics and the tear pattern of the injured meniscus visualized and probed during arthroscopic surgery, most articles recommend partial meniscectomy and peripheral side repair as necessary. Total meniscectomy status increases the contact stress on articular cartilage, resulting in a painful joint because progression of the degeneration of articular cartilage may induce osteoarthritis, similar to a non-discoid meniscus. Meniscectomy for discoid medial meniscus can yield promising short-term results and deteriorating long-term results, with secondary degeneration of cartilage in the medial compartment.

Upon intermediate-term follow-up of the current cases, the knee of patient 1 revealed complex re-tearing of the remaining meniscus 4 years after partial meniscectomy. The knees of patient 2 revealed degenerative tearing of the remaining meniscus and cartilage wear of the femoral condyle 3 years after the meniscectomy. We believe that partial meniscectomy does not restore a normal discoid medial meniscus, unlike the non-discoid meniscus, because it remains thick and liable to snapping or residual pain. Furthermore, most reported symptomatic discoid medial menisci exhibited horizontal cleavage tears, attributable to the presence of myxoid degeneration in the intrameniscal substance. These degenerated remaining menisci after meniscectomy may be at high risk of complicated re-tearing of the free margin or secondary degeneration of cartilage in the medial compartment in young and active subjects.

MAT is an effective biologic reconstruction method for a meniscectomized knee that reduces symptoms in the affected compartment. Although complications including tear of the allograft, synovitis, effusion, or infection have been reported, when considering only isolated MAT, the acceptable complication rate is 3.6%. In a long-term study, radiological progression of arthritis was halted in 35% of patients after MAT, indicating a potential chondroprotective effect. Some potential chondroprotective effect by which MAT reduces the progression of osteoarthritis have been suggested. The current cases had difficulties in daily activities and their occupations as young professional soldiers due to persistent pain in the medial compartment of knees after subtotal meniscectomy. MAT was performed using the bone plug technique in complicated bilateral discoid medial meniscus.

To our knowledge, follow-up of MAT of symptomatic bilateral discoid medial meniscus has not been reported previously. After over one year of follow-up after MAT, MRI showed sound peripheral healing of the joint capsule, and there was no frank extrusion of the allograft out of the tibiofemoral joint. After more than 2 years of follow-up after MAT, both patients remained free from pain. Lysholm and Tegner activity score was improved compared to before MAT. However, the patients’ daily activities and sports abilities as Tegner activity scale level 5 were limited in comparison with healthy individuals of the same age group. We should bear in mind the possibility of future re-tearing of the allograft meniscus or progression of cartilage degeneration.

Partial meniscectomy is the principal treatment method for symptomatic discoid medial meniscus and can yield promising short-term results. However, because deteriorating long-term results with re-tearing of remaining meniscus or secondary degeneration of cartilage of the medial compartment can occur in highly active young patients, activity modification to prevent possible injury may be recommended. Meniscal allograft transplantation may be an alternative option in highly active young patients undergoing complicated discoid medial meniscus to diminish pain, improve knee function, and prevent or delay degeneration.
