I. INTRODUCTION

The composite fermion approach has had a great number of extremely impressive successes in describing the physics of electrons in high magnetic fields. In this picture, fractional quantum Hall systems in total magnetic field \( B \) are described in terms of noninteracting "composite fermions" in an effective magnetic field \( B_{\text{eff}} = B - 2m\phi_0n \), where \( \phi_0 = hc/e \) is the flux quantum, \( n \) is the electron density, and \( m \) is a positive integer. This maps, for example, fractional quantum Hall states at filling fractions of the form \( \nu = n\phi_0/B = p/(2mp + 1) \) to integer quantum Hall states for the composite fermions at filling fraction \( \nu_{\text{eff}} = n\phi_0/|B_{\text{eff}}| = |\nu| \). We will denote such composite fermions with \( 2m \) flux quanta attached to them as \( 2m\text{CF} \).

Jain’s original approach to composite fermions constructed highly accurate trial wavefunctions for large numbers of electrons in high magnetic fields by taking simple wavefunctions for the noninteracting (composite) fermions in the effective magnetic field, multiplying by Jastrow factors, and then projecting the result into the lowest Landau level. The early successes of this method were impressive, despite the fact that the method was limited by the extreme numerical difficulty of performing projections for systems with more than roughly 10 electrons.

A major theoretical breakthrough came when Jain and Kamilla discovered a new way of writing composite fermion trial wavefunctions (described below), which involves a very minor modification of the projection. These new trial states seemed to be just as good as the originally proposed wavefunctions and could be numerically generated even for systems with many electrons (40 electrons or more). Since that time, many important studies have been achieved using this method. However, so far this method has been restricted to cases where the effective magnetic field has the same sign as the external magnetic field. Results using this method have been published for filling fractions of the form \( \nu = p/(2mp + 1) \) with \( p > 0 \) but not for \( p < 0 \). In the current paper, we extend the work of Jain and Kamilla so that we are able to handle states with \( p < 0 \). The \( p < 0 \) states take more computational resources than the case of \( p > 0 \), and the difference in the computational resources between the two cases increases with the absolute value of the effective flux. However, the computational problems turn out to be more severe for the smallest \(|\nu|\) where the number of particles in the system increases most slowly with each flux added. Fortunately, we probably need not go to particularly large systems to understand the physics of small \(|\nu|\). For large \(|\nu|\), describing the approach to the Fermi liquid-like composite fermion state, the system size is already large for relatively small effective flux, i.e. the difference in the computational requirements in the case of \( p > 0 \) and \( p < 0 \) become relatively less important.

Although the case of negative \( p \) has not previously been studied for large systems, we point out that for \( m = 1 \) the series of states with negative \( p \) and the series of states with positive \( p \) are essentially equivalent due to an exact particle-hole symmetry in the lowest Landau level. In fact, below, we exploit this symmetry to check the validity of our method. Once we have verified the method, we can study the properties of the \( m = 2 \) series for negative \( p \) and compare the results to those of the positive \( p \) members of this same series as well as to those of the \( m = 1 \) series.

The outline of this paper is as follows. In section II we briefly review the Jain-Kamilla method. As mentioned above, the method has only been used previously for the case of positive \( p \). In appendix A we show in detail how the crucial projection scheme of Jain-Kamilla can easily be generalized to handle negative \( p \) also. It is easy to see from the result how much additional numerical complexity is involved for negative \( p \). In section III we test our approach by examining the \( 2\text{CF} \) series \( \nu = p/(2p + 1) \). In particular, we examine ground state energies, excitation spectra, and energy gaps. We pay particular attention to the mass of the composite fermion and the scaling of the gap with \( p \). For \( p > 0 \), results are already available in the literature. For \( p < 0 \) we use our generalization of...
the Jain-Kamilla method to calculate energies directly, and we compare these energies to energies obtained by particle-hole conjugating the \( p > 0 \) series. Appendix B describes the particle-hole conjugation transformation in depth. This comparison establishes the accuracy of our method. In section IV we move on to examine the \(^4\text{CF}\) series of states \( \nu = p/(4p + 1) \). Again, for \( p > 0 \) some results are already available in the literature\(^5\)\-\(^7\). However, for \( p < 0 \) our results are new. Again, we examine ground state energies, excitation spectra, energy gaps, and composite fermion effective masses. (By using particle-hole conjugation, we could give results for filling fractions \( \nu = 1 - p/(4p + 1) \) similarly.) We are able to make some comparison of our energy gaps to the experimental work of Pan et al.\(^8\).

Throughout this paper we assume complete spin-polarization of the electrons. This should be a reasonable assumption for real experiments at sufficiently high magnetic fields.

\section{II. The Jain-Kamilla Method}

Jain’s original proposal\(^2\) was to construct trial wavefunctions for fractional quantum Hall states by writing

\[
\Psi_{\text{Jain}} = \mathcal{P} \left\{ \det \left[ \psi_i(\vec{r}_j) \right] \Phi_{0}^{2m} \right\},
\]

where the determinant is a Slater determinant of non-interacting single fermion wavefunctions \( \psi_i \) in effective magnetic field \( B_{\text{eff}} = B - 2mn\phi_0 \), and \( \mathcal{P} \) indicates projection to the lowest Landau level. Here, \( \Phi_0 \) is the wavefunction of a completely filled Landau level

\[
\Phi_0 = \prod_{i<j} (z_i - z_j),
\]

where \( z_j = (x_j + iy_j)/\ell_0 \) is the dimensionless complex coordinate on the plane, \( \ell_0 = \sqrt{\hbar c/\epsilon B} \) and the usual Gaussian factors \( \exp(-\frac{1}{2} \sum |z_i|^2) \) are understood to be included in the measure of the Hilbert space and will not be written explicitly for simplicity of notation.

Choosing a set of single particle wavefunctions \( \psi_i \) to fill the \( p \) lowest effective Landau levels (i.e., such that \( \det[\psi_i(\vec{r}_j)] \) represents the ground state of an integer quantum Hall state \( \nu = p \)), one obtains through Eq. 1 extremely good trial wavefunctions for fractional quantum Hall states \( \nu = p/(2mp + 1) \). As discussed above, the projection in Eq. 1 is exceedingly hard to implement for systems with more than roughly 10 electrons. For this reason, Jain and Kamilla\(^3\) looked for an essentially equivalent formulation that would be computationally simpler. In their approach they begin by rewriting the wavefunction as

\[
\Psi_{\text{Jain}} = \mathcal{P} \left\{ \det \left[ \psi_i(\vec{r}_j) J_j^m \right] \right\},
\]

where

\[
J_j = \prod_{k \neq j} (z_k - z_j)
\]

and then make the approximation that one can interchange the order of projection and taking the determinant to obtain a new trial wavefunction

\[
\Psi_{\text{JK}} = \det \left[ \tilde{\psi}_i(\vec{r}_j) \right] \Phi_0^{2m}
\]

with

\[
\tilde{\psi}_i(\vec{r}_j) = J_j^{-m} \mathcal{P} \left\{ \psi_i(\vec{r}_j) J_j^m \right\}.
\]

Although \( \Psi_{\text{JK}} \) appears to be a single Slater determinant, it is somewhat more complicated because each \( \tilde{\psi}_i(\vec{r}_j) \) is actually a function of all of the particle positions through \( J_j \). Nonetheless, this new trial wavefunction is far simpler to evaluate numerically. Furthermore, extensive numerical work\(^3\)\-\(^7\) has shown that for small systems \( \Psi_{\text{JK}} \) is just as good a trial state as \( \Psi_{\text{Jain}} \) and that both are extremely accurate\(^{16}\). In the original work by Jain and Kamilla, it was shown how to calculate \( \tilde{\psi} \) on a sphere for the case when \( B_{\text{eff}} \) has the same sign as the magnetic field \( B \) (i.e., \( p > 0 \)). In Appendix A we repeat the derivation for the case where \( B_{\text{eff}} \) has the opposite sign from \( B \) (i.e., \( p < 0 \)). A discussion is also given there of the relative computational effort required to perform the relevant computations numerically.

This technique allows one to also obtain low energy spectra of these fractional quantum Hall states, by similarly composite-fermionizing low energy excited states of noninteracting fermions as discussed in Ref. 4.

In this paper we will perform all calculations using a spherical geometry\(^9\) with a monopole of charge \( N_\phi \) flux quanta at the center. The composite fermions then see an effective flux \( 2q = N_\phi \) \( = N_\phi - 2m(N - 1) \). In the presence of this effective flux, single particle states are described by two quantum numbers, \( l \) and \( m \). Here \( l = |q| + n \) is the angular momentum with \( n = 0, 1, 2, \ldots \) corresponding to the “Landau level number” or “shell” index, and \( m \) is the \( z \)-component of angular momentum. A state with \( p \) filled composite fermion Landau levels corresponds to \( n = |p| - 1 \).

A low energy exciton is now formed by taking a composite fermion out of the highest occupied shell (or Landau level) \( l = l_F = |q| + |p| - 1 \) with some \( m_0 \) and putting it in the lowest unoccupied \( l = l_F + 1 \) shell with some \( m_e \). Choosing to work with states of zero total \( z \)-angular momentum, we take the state with \( m_e = -m_0 \) and write this state as \( |m_e \rangle \). Using vector coupling (Clebsh-Gordon) coefficients\(^{12}\) we can construct exciton eigenstates of angular momentum \( L \) as

\[
| \Xi_L \rangle = \sum_{m_e = -l_F}^{l_F} |m_e \rangle / l_F, \quad \left| m_e \right| + 1, \quad m_e |L, 0 \rangle \quad (7)
\]

which serve as extremely accurate trial wavefunctions for the low energy excited states of the above discussed composite fermion ground states.
III. PARTICLE-HOLE SYMMETRY AND RESULTS FOR $\nu = p/(2p + 1)$

Using particle-hole symmetry of the lowest Landau level, one can exactly map states at filling fraction $\nu$ into states at filling fraction $1 - \nu$ (so long as we maintain complete spin polarization). As mentioned above, in this paper we perform all calculations using a spherical geometry. On the sphere, the lowest Landau level has $N_\phi + 1$ single particle eigenstates with $N_\phi$ the total number of flux quanta penetrating the sphere. Thus states with $N$ electrons can be precisely mapped to their particle-hole conjugate states with $N_\phi + 1 - N$ electrons (i.e. with $N$ holes). In Appendix B we show that, on a sphere, given an eigenstate $\Psi$ with $N$ electrons and energy $E_\Psi$, one can write the energy $E_{\Psi}$ of its particle-hole conjugate wavefunction $\Psi$ as

$$E_{\Psi} = \left(1 - \frac{2N}{N_\phi + 1}\right)E_{\text{filled}} + E_\Psi,$$  

where $E_{\text{filled}}$ is the energy of the completely filled Landau level. This, of course, implies that the excitation spectrum of any given state is precisely the same as the excitation spectrum of its particle-hole conjugate state.

We will now focus on $^3\text{CF}$ states of the form $\nu = p/(2p + 1)$. The state with $p$ is particle-hole conjugate of the state with $p \rightarrow (p-1)$. (For example, $\nu = 1/3$ which is $p = 1$ is conjugate of 2/3 which is $p = -2$). Extensive numerical work has already been performed for positive $p$, calculating accurate ground state energies and energy gaps.$^3$-$^7$ Using Eq. 8 this means that we already know the ground state energies and energy gaps for negative $p$. Here, however, we calculate these quantities directly using our negative $p$ trial wavefunctions and compare to the particle hole conjugated results to establish the validity of our approach.

Table I summarizes the numerical results for the ground state energies of states in this series calculated using Monte-Carlo.$^3$-$^7$.$^{17}$

The ground-state energies we obtain using negative $p$ trial wavefunctions show an outstanding agreement with the values obtained by particle hole conjugating positive $p$ trial wavefunctions. We observed slight differences on the fourth significant digit, that show that the trial state with composite fermions in positive effective flux is very slightly better than the one with negative effective flux.
confirm the validity of our approach to calculating CF wavefunctions at negative effective flux, which enables us to consider in the following section filling fractions above 1/4 in the series \( \nu = p/(4p + 1) \), that were previously inaccessible.

IV. RESULTS FOR \( \nu = p/(4p + 1) \)

The \(^4\)CF series of composite fermion states, corresponding to filling fractions around \( \nu = 1/4 \), has been the subject of some recent experimental work, yet the branch of filling fractions above 1/4 has been mostly inaccessible to numerical investigations. The numerical approach we took for examining these states permits us to calculate the excitation spectra for systems with a moderate number of effective magnetic flux quanta \( N_{\phi}^{\text{eff}} = 2q \) for the CF-system. For negative \( p \), the calculational complexity of the wavefunction increases with \( q \), consequently the achievable system size is reduced compared to the systems with positive \( p \). For this very reason, extrapolation of the results to infinite system size in order to obtain the gap in the thermodynamic limit, and thus the mass of the CF, is difficult for these states. Nonetheless, interesting observations can be made already from the finite size data. The excitation spectra associated with \( p \) and \(-p\) show a striking similarity in structure at the same system size (see Fig. 2). These similarities, though apparent already for \( |p| = 2 \) become even more clear as \( |p| \) increases and \( \nu = 1/4 \) is approached. Note that same values for the relative angular momentum \( L \) translate into different absolute wave vectors of the corresponding excited state for different filling factors, since \( k \propto \frac{L}{\sqrt{N_{\phi}}} \).

Table II summarizes the numerical results for the groundstate energies and gaps of states around \( \nu = 1/4 \), and Figure 2 shows several examples of excitation spectra revealing the above mentioned similarity.

It is interesting to note that the \( p \leftrightarrow -p \) similarity in spectra found here differs from the particle-hole symmetry correspondence of \( p \) with the \(-p\) \(-1\) states in the \( \nu = p/(2p + 1) \) series shown above in section III. One might naively expect that the particle-hole symmetry \( p \leftrightarrow -p - 1 \) for states in the \(^4\)CF series \( \nu = p/(2p + 1) \) above survives the composite fermionization attachment of two more Jastrow factors and results in an approximate symmetry for \( \nu = p/(4p + 1) \) states. For example, we could take the symmetry related \( m = 1 \) pair \( (p = -3,N = 12) \) and \( (p = 2,N = 10) \) at \( N_{\phi} = 21 \) on Table I and add two Jastrow factors so \( N_{\phi} \rightarrow N_{\phi} + 2(N - 1) \) resulting in an approximate symmetry relating \( (p = -3,N = 12,N_{\phi} = 43) \) to \( (p = 2,N = 10,N_{\phi} = 39) \) in Table II. However, when we examine the overall shape of the resulting excitation spectra, we find very little relation between the two spectra related by \( p \leftrightarrow -p - 1 \) for \(^4\)CFs. In contrast we see in Figure 2 that the \( p \leftrightarrow -p \) related states have quite similar dispersions, and the similarity appears to increase with increasing \( |p| \).
TABLE II: Numerical results from Monte Carlo calculations of $^4$CF wavefunctions for groundstate energies and gaps at filling fraction $\nu = p/(4p + 1)$, given in units of $e^2/\epsilon\ell_0$. Alongside the newly calculated negative $p$ Quantum Hall states of this series above $\nu = 1/4$, we give the results for states with the respective positive $p$ and equal particle number for comparison. We find that the similarity between the results for $p$ and $-p$ increases with increasing $p$. Two excitation energies are given from the spectra of neutral excitations: the magneto-roton gap as the lowest lying excitation and the large $k$ gap measured at the highest possible angular momentum. Extrapolation to the thermodynamic limit has been performed using the above given data by a simple linear regression over the inverse particle number (see Figure 3). In the case of groundstate energies, this extrapolation is based on density corrected values$^{13}$ ($E_{\nu=0} = E_\nu \sqrt{pN_e/N}$).

The existence of this similarity is perhaps not completely unexpected. Within a mean-field version Chern-Simons theory of composite fermions$^{11}$ one would expect the gaps to have this $p \leftrightarrow -p$ symmetry as well as having a symmetry in the excitation spectrum. However, beyond mean field theory, there is no clear reason to expect the symmetry to be preserved except for at large $|p|$.

We comment that another interesting test of our approach can be obtained by constructing a trial wavefunction for $\nu = 1/3$ as the $p = -1$ member of the $\nu = p/(4p + 1)$ series. We find that the ground state energy of this wavefunction is, within numerical precision, precisely the same as that of the Laughlin $\nu = 1/3$ trial wavefunction, which leads us to believe that we have precisely constructed that state. Similarly, we can examine the excitation spectrum of $\nu = 1/3$ by using a $^2$CF wavefunction of the series $p/(2p + 1)$ with $p = 1$ or by using a $^4$CF wavefunction of the series $p/(4p + 1)$ with $p = -1$. We find that the spectra obtained in these two approaches are quite similar to each other (albeit not quite identical), which gives us still further confidence in our approach. The values of the magneto-roton gap appear to be almost exactly the same in both cases. Yet, examining the large $k$ gap, the $^4$CF trial wavefunction using negative flux ($p = -1$) yields a slightly larger value, which decreases slightly more rapidly with the system size though, and seems to extrapolate to almost the same value at infinite $N$ (see Figure 3).

Figure 3 shows the extrapolation to the thermodynamic limit of the data given in Table II, comparing gaps at $p$ with those of states at $-p$. A comparison of the excitations at $\nu = 1/3$ considered in the two different manners discussed above is also displayed there. Further, this figure gives us an idea of the quality of our extrapolation. Where the extrapolation is not particularly smooth, we cannot claim to deliver more than a rough result. The
extrapolation of \( p = \pm 2 \) appears to be the most difficult, since it is not easy to distinguish a clear linear dependence of the large \( k \) gap as a function of \( N^{-1} \) for the initial data set. The reason for this problem appears to be that the magnetoroton gap is located at a large value of \( L \), so that in the smaller systems, the magnetoroton gap is located very close to the largest \( k \) available, or even coincides with this point. For the \( p = 2 \) case, we can see the error in this extrapolation clearly by comparing our extrapolated result to a result of a similar calculation using larger system sizes from Ref. 6. This comparison is show in Figure 4 (see below). We might guess that the error in extrapolation for \( p = -2 \) is of similar magnitude.

In order to obtain the composite fermion effective mass, we equate the activation gap \( \Delta \) (determined from the excitation energy at the maximum angular momentum, i.e. biggest particle-hole separation) to the cyclotron energy of CFs in their effective magnetic field:

\[
\Delta_{\nu(m,p)} = \frac{\hbar e |B_{\text{eff}}|}{m^* c} = \frac{\hbar^2}{2m(p+1)|m^*|_0^\delta}.
\]  

(9)

Since the gap is measured in units of the Coulomb interaction, we write \( \Delta = (e^2/\epsilon_0)\delta \). Further taking into account \( \epsilon_r = 12.8 \) for GaAs and the free electron mass as our point of reference, we find the dimensionless normalized effective mass \( m^*_\text{nor} = m^*/(m_0 c^2 B_c(T)) \) to be given by \( m^*_\text{nor} = 0.0264/(2m(p+1)|\delta|) \). The CF-masses we obtain are displayed in Figure 4 together with the large \( k \) gaps from which they are deduced. In addition, for \( \nu < 1/4 \) (positive \( p \)) we have shown data from Ref. 6 where larger systems were used than we have used here (When we also use larger system sizes, our results agree very well with those of Ref. 6). For \( \nu = 1/3 \), as discussed above, we have shown results that treat this either as a \( p = -1 \) point of the \( p/(4p+1) \) series or a \( p = 1 \) point of the \( p/(2p+1) \) series. For the latter case, we have likewise included the result from the above mentioned larger system calculation.

In Figure 4, we have intentionally displayed data extrapolated from a restricted set of small systems sizes with positive \( p \) so as to match the same set of system sizes that we study for negative \( p \) where we cannot go to very large systems. One can estimate the finite size error for our negative \( p \) calculations by examining the deviations between these restricted extrapolations at positive
p compared to the larger system calculations of Ref. 6 (also displayed in our figure).

The behavior of the negative p fractions seems to roughly mirror the behavior of the positive p fractions, at least for |p| ≥ 2. As was seen previously in Ref. 6 for p > 0 it is seen that the effective mass increases with |B_{eff}|. As ν = 1/4 is approached from either side, it is not clear if the effective mass will converge to a constant as would be predicted by theory (up to logarithmic corrections\(^{33}\)). In the experiments of Ref. 8, a striking asymmetry of the effective mass between the high field and low field sides of ν = 1/4 has been observed. While we cannot rule out some asymmetry from our data, we certainly cannot claim to see the extremely strong differences that are observed experimentally. This, however, is not surprising. Experimentally, the asymmetry is attributed to the proximity of a Wigner crystal state\(^6\). Since we are using a trial wavefunction approach, we should not see the effects of any imminent phase transition.

Perhaps the most interesting data point in Figure 4 is the one at ν = 1/3. Whether we treat this point as the p = −1 member of the series p/(4p + 1) or the p = 1 member of the series p/(2p + 1), we find almost identical results of a very large gap, which establishes a continuity between the CF masses around ν = 1/2 and ν = 1/4. Furthermore, we note that this point is quite asymmetric with its reflection at ν = 1/5. Certainly the hypothesis of constant effective composite fermion mass does not extend all the way from ν = 1/4 out to both ν = 1/5 and ν = 1/3. Below quarter filling, one observes a continuous increase of this mass. A similar trend appears at small values of the effective magnetic field above this point, but then the mass drops down again at ν = 1/3, the final point of this series.

Generally, our values for the effective mass seem to be lower than those measured in the experiments of Ref. 8 by a factor of roughly 2.5. This error is rather expected, since similar discrepancies have been observed in previous studies based on the composite fermion picture\(^6\). It is known, however, that taking into account the finite width of the 2D electron gas changes the interaction so as to increase the effective mass\(^8\).

We note that we are not able to find any evidence of the divergence of m* as we approach ν = 1/4 from either side, which is observed experimentally in Ref. 8. This is not surprising for several reasons. First of all, the experiment only sees strong divergences extremely close to ν = 1/4 – which we cannot access numerically. Furthermore, one might suspect that the disorder might be the source of the divergences in the measurements used by Pan. More importantly, however, even if there were genuine infra-red divergences\(^{14}\) of the effective mass as ν = 1/4 is approached, one would not necessarily expect such divergences to be properly represented in a trial wavefunction approach.

We emphasize that the most important achievement of this paper is not any particular numerical result. If genuine numbers were desired for comparison to experiment, we would want to use a more realistic interaction, accounting for finite well width\(^6\), as well as perhaps Landau-level mixing, and we would want to use a more powerful computer to analyze ever larger systems. Instead we would like to emphasize in this paper that we have clearly demonstrated that we can extend the approach of Jain and Kamilla\(^3\) to treat negative effective magnetic field, and we can study these negative p composite fermion wavefunctions for reasonably large systems, which has not been done before. In this paper we have tested this method by using particle-hole symmetry for the \(^2\)CF series and we have found our method to be quite accurate. We have then applied this method to \(^4\)CFs to study, for the first time, large systems for filling fractions p/(4p + 1) with negative p. Our main physical result is that the effective mass appears to be roughly symmetric around and close to ν = 1/4 although larger system calculations would be desirable.

Appendix A: CF wavefunctions with negative effective flux

The starting point for the composite fermion trial wavefunctions is the single particle eigenfunctions of the quantum mechanical problem of a particle in a magnetic monopole field on a sphere. (We use spherical coordinates with the azimuth \(\theta\) ranging from 0 to \(\pi\), and \(\phi\) the longitude ranging from 0 to \(2\pi\)). The monopole harmonics are given by

\[
Y_{q,n,m}(\Omega) = 2^m M_{q,n,m}(1-x)^{n/2}(1+x)^{\beta/2} P_{q}^{\alpha,\beta}(x)e^{im\phi}
\]

with \(\alpha = -q - m\), \(\beta = q - m\), \(g = |q| + n + m\), \(x = \cos \theta\),

\[
M_{q,n,m} = \frac{2|q| + 2n + 1}{4\pi n!}[(|q| + n + m)!/([q] + n + m)!(|q| + n)!]
\]

and \(P_{q}^{\alpha,\beta}(x)\) are the Jacobi polynomials. This monopole harmonic represents an eigenstate of a particle on a sphere in a radial magnetic field with \(2q\) flux quanta penetrating the sphere, where a positive sign refers to outwards pointing flux. Here, the angular momentum of the sphere in a radial magnetic field with \(2q\) flux quanta ranging from 0 to \(2\pi\) represents an eigenstate of a particle on a sphere in a radial magnetic field with \(2q\) flux quanta penetrating the sphere. Here, the angular momentum \(l\) and \(m\) are the LL index \(l\) and \(m\) of the eigenstate, respectively.

This expression can equally well be obtained from the Haldane gauge, where the singularities of the vector potential are chosen to be located symmetrically on both north- and southpole of the sphere. Here, we focus on the case where \(q < 0\), since the \(q > 0\) case has already been discussed in detail in Ref. 3. For the rest of this paragraph, we thus assume \(q < 0\). Expanding the Jacobi polynomials in terms of the spinor coordinates \(u = \cos(\theta/2)e^{-i\phi/2}\) and \(v = \sin(\theta/2)e^{i\phi/2}\), one obtains

\[
Y_{q,n,m}^{<0}(\Omega) = (-1)^n M_{q,n,m} (u^*)^{-q}v^{m}v^{-m}u^{-q} \times \sum_{s=0}^{n} (-1)^s \binom{n}{s} \binom{2|q| + n}{|q| + m + s} \binom{u^*u}{v^*v}^{-n-s}.
\]

This expression can equally well be obtained from the relation for complex conjugation of the monopole harmonics, if one corrects Kamilla's formula by replacing \(q\) by \(|q|\) in the appropriate places. We now use the \(Y_{q,n,m}^{<0}\) as single particle wavefunctions (written as \(\psi_i\) in the main text) and composite fermionize by attaching Jastrow factors to each of the basis states \(Y_{q,n,m}^{<0}\) separately, by expanding \(J^P_i\) in this basis. In general multiplication by a basis state \(Y_{q,n,m}^{<0}\) followed by projection can be described as a linear operator called hereafter \(\mathcal{P}\).

First, we remark that the Jastrow factor is a LLL function, with \(q' = p(N - 1)\) zeros in \(u_j\), i.e. it is a LLL wavefunction for flux \(q' > 0\). Since \(N\) is in general a big number, we have \(q' \gg |q|\). The resulting wavefunction, in turn, has to be a valid wavefunction for a total number of flux \(Q = q + q' > 0\). Secondly, since projection is a linear operation, we may consider the action of projection on each of the basis states \(Y_{q,n,m}^{<0}\), separately, by expanding \(J^P_i\) in this basis. In general multiplication by a basis state \(Y_{q,n,m}^{<0}\) followed by projection can be described as a linear operator called hereafter \(\mathcal{P}\).

\[
\mathcal{P}Y_{q,n,m}^{<0} = \mathcal{P}_{q,n,m}Y_{q,n,m}^{<0}.
\]

Since we know the entire basis of the subspace that we project upon, namely the LLL for flux \(Q\) with states \(|M\rangle\), and \(|M| \leq Q\), the projection operator is \(\sum_M |M\rangle\langle M|\).

We now show, how this leads to an expression for \(\mathcal{P}_{q,n,m}\) as a differential operator in the coordinate representation, in which (A3) becomes

\[
\sum_{M=-Q}^{Q} Y_{q,n,m}^{<0}(\Omega) \int d\Omega' Y_{0,M}^{*}(-\Omega') Y_{q,n,m}^{<0}(\Omega') = \mathcal{P}_{q,n,m} Y_{q,n,m}^{<0}(\Omega).
\]

Integration over the longitudinal angle \(\phi\) singles out one nonzero scalar product for \(M = m + m'\), and the one remaining integral over the azimuthal angle \(\theta\) yields a well known binomial coefficient. Simplifying the normalization factors of \(Y_{q,n,m}^{<0}\), on both sides, we have:

\[
(1)^n M_{q,n,m} \sum_{s} (-1)^s \binom{n}{s} \binom{2|q| + n}{|q| + m + s} \times (N_{Q,0,M})^2 \frac{(q' - m' + s)!}{(2q' + n + 1)!} \times v^{q + m + m'} u^{q + m + m'} = \mathcal{P}_{q,n,m} Y_{q,n,m}^{<0}.
\]

Using the explicit form of the normalization

\[
(N_{Q,0,M})^2 = \frac{(2Q + 1)!}{4\pi(Q + M)!} / (Q - M)!.
\]

and remarking that the fractions of factorials that are left in this expression equal those that appear by the multiple derivation of a monomial \(u^k\)

\[
\left( \frac{\partial}{\partial u} \right)^s u^{q + m + s} = \frac{(s + q + m')!}{(Q + M)!} u^{Q + M},
\]

we may deduce \(\mathcal{P}_{q,n,m}\) by comparison of both sides:

\[
\mathcal{P}_{q,n,m} Y_{q,n,m}^{<0} = \frac{(2Q + 1)!}{(2q' + n + 1)!} (-1)^n M_{q,n,m} \sum_{s=0}^{n} (-1)^s \binom{n}{s} \binom{2|q| + n}{|q| + m + s} \times \left( \frac{\partial}{\partial u} \right)^{|q| + m + s} u^{s} \left( \frac{\partial}{\partial v} \right)^{|q| - m + n - s} v^{n-s}.
\]
Let us remark that this result reproduces the known result, that the projection on the LLL is achieved by performing the habitual procedure of moving all $u^*$’s to the far left, and replacing them with derivatives according to

$$u^* \to \frac{\partial}{\partial u}, \quad v^* \to \frac{\partial}{\partial v}. \quad (A9)$$

Nevertheless, performing this explicit projection gives us a supplementary information in the form of a weight factor \(\frac{(2Q+1)!}{(2q+n+1)!}(-1)^n M_{q,n,m} \times \)

$$ \sum_{s=0}^{n} (-1)^{n-s} \left( \frac{2|q|+n}{|q|+m+s} \right) \times$$

$$u_i^s v_i^{n-s} [\hat{U}_i^{q|+m+s} \hat{V}_i^{q|+m-n-s-1}]. \quad (A15)$$

Of course, this only appears to be a one particle wavefunction, since there is an implicit dependence of the positions of all other electrons in the system hidden in the operators \(\hat{U}_i\) and \(\hat{V}_i\). The complexity of this expression increases with the total number of derivatives per term, given by \(N_{\partial} = 2|q| + n\) for negative \(q\) compared to \(N_{\partial} = n\) for positive effective flux.

**Appendix B: Particle-hole Conjugation**

In the lowest Landau level, on the sphere, there are \(N_\partial + 1\) single particle eigenstates where \(N_\partial\) is the flux through the sphere. We label these eigenstates by the \(z\)-component of their angular momentum \(m\).

For a two-body interaction we can write the Hamiltonian as

$$H = \sum_{m_1,m_2,m_3,m_4} V_{m_1,m_2,m_3,m_4} c_{m_1}^\dagger c_{m_2} c_{m_3} c_{m_4}. \quad (B1)$$

As usual, the normal ordering of the operators accounts for the uniform positive background. As usual, the fermion operators have anticommutation relations \(\{c_i^\dagger, c_j\} = \delta_{i,j}\). The interaction matrix \(V\) must have the following symmetries

$$V_{m_1,m_2,m_3,m_4} = -V_{m_2,m_1,m_3,m_4} = -V_{m_1,m_2,m_4,m_3} = V_{m_4,m_3,m_2,m_1}. \quad (B2)$$

Furthermore, for any rotationally (translationally) invariant interaction, we must have angular momentum conservation, which implies that the matrix element is zero unless

$$m_1 + m_2 = m_3 + m_4. \quad (B3)$$

We define the vacuum state \(|0_z\rangle\), to be the state which contains no electrons at all. The filled Landau level, which we can also think of as the vacuum for holes is written as \(|0_h\rangle = |\text{Filled}_z\rangle = \prod_m c_m^\dagger |0_z\rangle\). It is convenient to introduce creation and annihilation operators \(d, d^\dagger\) for holes, given by \(d_i = c_i^\dagger, \quad d_i^\dagger = c_i\) which also obey the usual anticommutations \(\{d_i^\dagger, d_j\} = \delta_{i,j}\). We now rewrite the Hamiltonian in terms of these hole operators. Using the commutation relations as well as above described
symmetries of $V$ we obtain

$$H = \sum_{m_1, m_2, m_3, m_4} V_{m_1, m_2, m_3, m_4} d_{m_1}^\dagger d_{m_2} d_{m_3} d_{m_4}^\dagger$$

$$= 2 \sum_{m} U_{m} (1 - 2 d_{m}^\dagger d_{m}) + H_d,$$  \hspace{1cm} (B4)

where

$$U_{m} = \sum_{m_2} V_{m_1, m_2, m_2, m}$$  \hspace{1cm} (B5)

and

$$H_d = \sum_{m_1, m_2, m_3, m_4} V_{m_1, m_2, m_3, m_4} d_{m_1}^\dagger d_{m_2} d_{m_3} d_{m_4}^\dagger.$$  \hspace{1cm} (B6)

We show below that for any rotationally invariant interaction, $U_{m}$ is actually independent of $m$. Furthermore, it is very easy to show that the energy of the entirely filled Landau level is given by

$$E_{\text{filled}} = 2 \sum_{m_1, m_2} V_{m_1, m_2, m_2, m_1} = 2 \sum_{m} U_{m}.$$  \hspace{1cm} (B7)

Thus we have

$$H = \left(1 - \frac{2N_{h}}{N_{\phi} + 1}\right) E_{\text{filled}} + H_d,$$  \hspace{1cm} (B8)

and $N_{h}$ is the number of holes (i.e., the eigenvalue of $\sum_{m} d_{m}^\dagger d_{m}$).

A general state containing $N$ electrons in the LLL can be written as:

$$|\Psi\rangle = \sum_{\{m_i\}} a_{m_1, \ldots, m_N} c_{m_1}^\dagger \cdots c_{m_N}^\dagger |0\rangle.$$  \hspace{1cm} (B9)

To particle-hole conjugate this state we construct

$$|\bar{\Psi}\rangle = \sum_{\{m_i\}} a_{m_1, \ldots, m_N}^* d_{m_1}^\dagger \cdots d_{m_N}^\dagger |0\rangle,$$  \hspace{1cm} (B10)

which is now a state containing $N$ holes, or $N_{\phi} + 1 - N$ electrons. Note that both of these states “live” in the same lowest Landau level which has $N_{\phi} + 1$ single particle eigenstates (indexed by $m$).

Now, if $\Psi$ is an eigenstate of $H$ with eigenvalue $E_{\Psi}$ (assumed to be real), then, since $H_d$ has precisely the same structure as $H$ we see that $\bar{\Psi}$ is an eigenstate of $H_d$ with the same eigenvalue. Thus, we obtain the particle hole conjugation relation

$$E_{\Psi} = \left(1 - \frac{2N_{h}}{N_{\phi} + 1}\right) E_{\text{filled}} + E_{\bar{\Psi}}.$$  \hspace{1cm} (B11)

Lemma: $U_{m}$ is independent of $m$:

If an interaction is rotationally invariant, we can choose any rotation $R$ and write

$$V_{m_1, m_2, m_3, m_4} = \sum_{m'_1, m'_2, m'_3, m'_4} D_{m_1, m'_1}^l(R) D_{m_2, m'_2}^l(R) V_{m'_1, m'_2, m'_3, m'_4} [D_{m_3, m'_3}^l(R)]^* [D_{m_4, m'_4}^l(R)]^*,$$  \hspace{1cm} (B12)

where the $D$’s are rotation matrices as in Ref. 12 and $l = 2N_{\phi}$. Setting $m_2 = m_3$, and $m_1 = m_4 = m$ and summing over $m_2$ as prescribed in Eq. B5 we obtain

$$U_{m} = \sum_{m'_1, m'_2} D_{m_1, m'_1}^l(R) V_{m'_1, m'_2, m'_3, m'_4} [D_{m_3, m'_3}^l(R)]^*,$$  \hspace{1cm} (B13)

where we have used the orthogonality$^{12}$

$$\sum_{m_2} D_{m_2, m'_2}^l(R) [D_{m_3, m'_3}^l(R)]^* = \delta_{m'_3, m'_3}$$  \hspace{1cm} (B14)

as well Eq. B3. Since Eq. B13 must be true for any rotation, we can integrate over all rotations and use$^{12}$

$$\int dR D_{m_1, m'_1}^l(R) [D_{m_3, m'_3}^l(R)]^* = \text{constant},$$  \hspace{1cm} (B15)

independent of $m$, which shows that $U_{m}$ is independent of $m$.

We note in passing, that one could certainly construct several other trial wavefunctions which project in slightly different ways. For example, for \( m > 1 \) we might consider
\[
\tilde{\psi}(\vec{r}_i) = \mathcal{P} \{ \psi_i(\vec{r}_j) J_{m_1}^{m_2} \} J_{m}^{m}
\]
with \( m_1 + m_2 = m \) (and \( m_1 \geq 1 \)). In the cases we have checked we have found that wavefunctions built with this version of \( \tilde{\psi} \) are also extremely similar to those built from Eq. 6.

A subtlety in this process results from the observation that the wavefunction, calculated as described in the appendix A by separating it into a Slater-determinant of the projected pseudo single-particle-wavefunctions and a Jastrow-factor, tends to produce numerical instabilities in the determinant algorithm. This is easily understood, since two particles approaching each other at a distance \( d \) will cause the respective \( \tilde{\Psi}_i \) to grow as \( \tilde{\Psi}_i \propto d^{-\left(\left| q \right| + n \right)} \) in the same manner, producing two linearly dependent columns in the matrix. Now, due to numerical errors, instead of obtaining zero when two columns become the same, the evaluation yields numerical errors following approximately the same power law behavior, that will dominate the result. Since the short distance behavior of the wavefunction is known, extrapolation allows us to correct for such events that occur with a probability of less than \( 10^{-4} \) in all of the presented calculations.

Note that Pan et al. use a different normalization for \( m^* \), which amounts to a slight rescaling as follows: \( m^*_\text{Pan} = \sqrt{B_{1}/B_{1/4}} m^* \).

In this appendix, we note the number of flux pairs attached to each CF as \( p \), according to Kamilla's notation, whereas \( m \), that had been used for this purpose in section II to comply with the common notation for the filling fractions of Jain's series, is already used for the eigenvalue of \( L_z \) here.
