The Feynman path-integral variational approach to the polaron problem[1], along with the associated FHIP linear-response mobility theory[2], provides a computationally amenable method to predict the frequency-resolved temperature-dependent charge-carrier mobility, and other experimental observables in polar semiconductors. We show that the FHIP mobility theory predicts non-Drude transport behaviour, and shows remarkably good agreement with the recent diagrammatic Monte-Carlo mobility simulations of Mishchenko et al.[3] for the abstract Fröhlich Hamiltonian.

We extend this method to multiple phonon modes in the Fröhlich model action. This enables a slightly better variational solution, as inferred from the resulting energy. We carry forward this extra complexity into the mobility theory, where it shows richer structure in the frequency and temperature dependent mobility, due to the different phonon modes activating at different energies.

The method provides a computationally efficient and fully quantitative method of predicting polaron mobility and response in real materials.

I. INTRODUCTION

An excess electron in a polar semiconductor polarises and distorts the surrounding lattice. This polarisation then attempts to localise the electron, forming a quasiparticle state known as the polaron.

When the electron-phonon coupling is large, the extent of the polaron wavefunction becomes comparable to the lattice constant and a small polaron is formed where details of the interaction with the atoms are important in determining polaron properties, but the polaron itself is localised. Many studies have investigated the properties of small polarons[4–10], where many analytical and numerical studies have primarily focused on the Holstein model with a short-range electron-phonon interaction[4].

If the competition between the localising potential and the electron kinetic energy results in a large-polaron state, larger than the unit cell, a continuum approximation is valid and the details of the interaction with the atoms can be ignored, but the polaron itself is a dynamic object. The most simple large polaron model was introduced by Fröhlich[11], of a single Fermion (the electron) interacting with an infinite field of Bosons (the phonon excitations of the lattice). A major simplification with regards to real materials is assuming that only one phonon mode (which is the longitudinal optical mode, with electrically mediated electron-phonon interaction), and that this mode is dispersionless. The reciprocal-space integrals then become analytic with closed form. This Fröhlich model is described by the Hamiltonian

$$\hat{H} = \frac{\mathbf{p}^2}{2m^*} + \sum_k \hbar \omega_0 a_k^+ a_k + \sum_k (V_k a_k e^{i\mathbf{k}\cdot\mathbf{r}} + V_k^* a_k^+ e^{-i\mathbf{k}\cdot\mathbf{r}}).$$

(1)

Here $\mathbf{r}$ is the electron vector position, $\mathbf{p}$ its conjugate momentum, $m^*$ the electron effective mass, $\hbar$ the reduced Planck constant, $\omega_0$ the longitudinal optical phonon frequency, $a_k^+, a_k$ the phonon creation and annihilation operators with phonon wavevector $\mathbf{k}$. The electron-phonon coupling parameter is

$$V_k = \frac{2\hbar\omega_0}{|\mathbf{k}|} \left( \sqrt{\frac{\hbar}{2m^*\omega_0\Omega_0}} \right)^{\frac{1}{2}}. \quad (2)$$

Here $\Omega_0$ is the unit cell volume, $\alpha$ is Fröhlich’s dimensionless interaction parameter and other variables are as above. The model is entirely characterised by the unitless parameter $\alpha$.

Though this seems highly idealised, the $\alpha$ parameter is a direct function of the semiconductor properties: an effective mass $m^*$ (modelling the relevant bandstructure of the charge carrier), a phonon frequency $\omega_0$ (the quantisation of the phonon field), and the dielectric electron-phonon coupling between them (which dominates for polar materials[12]),

$$\alpha = \frac{1}{\pi} \left( \frac{1}{\epsilon_{\text{optic}}} - \frac{1}{\epsilon_{\text{static}}} \right) \frac{e^2}{\hbar\omega_0} \left( \frac{2m^*\omega_0}{\hbar} \right)^{\frac{1}{2}}. \quad (3)$$

Fröhlich’s Hamiltonian, though describing a simple physical system of a single effective mass electron coupled to a single-frequency phonon field, has resisted exact solution. This is a quantum field problem, as the phonon occupation numbers can change.

One celebrated approximation is Feynman’s variational path-integral approach\cite{1}. This method is surprisingly accurate\cite{13} considering the light computational effort, and applies for the full range of the Fröhlich electron-phonon coupling parameter, without having to make any weak- or strong-coupling approximation. The method was extended by Feynman-Hellwarth-Iddings-Platzman\cite{2} (commonly referred to as ‘FHIP’) to offer a prediction of temperature dependent mobility (in the linear-response regime) for polaron materials, without any empirical parameters, and without resorting to perturbation theory. This method was alternatively derived and used by Peeters and Devreese\cite{14–17}. The textbook definition of the ‘FHIP’ dc-mobility is an asymptotic solution recovered from a power series expansion of the model action around a solvable quadratic trial action. The resultant impedance function is well defined and analytic across all frequencies, temperatures and polaron couplings ($\alpha$). A generalisation to finite temperatures was made by Osaka\cite{18}, and the addition of an external driving force by Castiglano and Kokantoni\cite{19,20}, and Saitoh\cite{21}.

Hellwarth and Biaggio\cite{22} provide a method to replace the multiple phonon modes of a complex material with a single effective frequency and coupling. This approach has been used by ourselves\cite{23–25} and others\cite{26} to predict phenomenological properties of charge-transport for direct comparison to experiment.

In this paper we first describe the Feynman variational quasi-particle polaron approach\cite{1}, providing a consistent description with modern nomenclature and notation. We then show that the FHIP mobility theory\cite{2} predicts non-Drude transport behaviour, and agrees closely with recent diagrammatic Monte-Carlo mobility predictions of Mishchenko et al.\cite{3}, for the abstract Fröhlich Hamiltonian.

Second we extend the method to more accurately model complex real materials by explicitly including multiple phonon modes. Taking a multimodal generalisation of the Fröhlich Hamiltonian we derive a multimodal version of the Feynman-Jensen variational expression for the free energy at all temperatures, and then follow the methodology of FHIP\cite{2}, to derive expressions for the temperature- and frequency-dependent complex impedance.

Using the example of the well-characterised methylvammonium lead-halide (MAPbI$_3$) perovskite semiconductor, we provide new estimates of dc mobility and complex conductivity, which can now be directly measured with transient Terahertz conductivity measurements\cite{25}.

A key technical discovery during this work is that direct numerical integration of the memory function $\chi(\Omega)$ of FHIP\cite{2} (required to calculate the polaron mobility), rather than the commonly used contour-rotated integral, has more easily controlled errors for frequency-dependent properties. This is significant as many previous attempts\cite{2,22,23,27} (including ourselves), numerically evaluate the contour-rotated integral using complicated and computationally expensive power-series expansions in terms of special functions. This can be avoided entirely.

As this method requires a relatively trivial amount of computer time, has controlled errors (no Monte-Carlo sampling, or analytic continuation, limitations), and offers scope for further expansion and refinement, we suggest that it will be useful to predict polar semiconductor transport properties, particularly in the computational identification of new semiconductors for renewable energy applications.

II. THE PATH INTEGRAL APPROACH TO THE FRÖHLICH POLARON

A. Feynman variational approach

The 1955 Feynman variational approach\cite{1} casts the Fröhlich polaron problem into a Lagrangian path and field integral (the model action), and then integrates out the infinite quantum field of phonon excitations. The result is a remapping to an effective quasi-particle Lagrangian path integral, where an electron is coupled by a non-local two-time Coulomb potential to another fictitious massive particle, representing the disturbance in the lattice generated by its passage at a previous time. The density matrix $ρ(r', r''; h\beta)$ within an imaginary time $i h\beta$ is

$$ρ(r', r''; h\beta) = \int_0^{r(hβ)=r''} D\tau(\tau) exp\left\{\left(-\frac{S[ρ(\tau)]}{h}\right)\right\}.\tag{4}$$

The model action $S$ for the Fröhlich polaron is

$$S[ρ(τ)] = \frac{m^*}{2} \int_0^{h\beta} dτ \left(\frac{dρ(τ)}{dτ}\right)^2 - \frac{(h\omega_0)^2}{2\sqrt{2m^*}} \frac{α}{2},\tag{5}$$

and where

$$g_ω(τ) = \frac{\cosh(ω_0(τ - hβ/2))}{\sinh(hω_0/2)}\tag{6}$$

is the imaginary-time phonon correlation function.

We cannot easily evaluate the path-integral for the 1/τ Coulomb potential, so Jensen’s inequality, $\langle\exp\{f\}\rangle ≥ \exp\{\langle f \rangle\}$, is used to approximate the effective Lagrangian by an analytically path-integrable non-local two-time quadratic Lagrangian (the trial action), $S_0$,

$$S_0[ρ(τ)] = \frac{m^*}{2} \int_0^{h\beta} dτ \left(\frac{dρ(τ)}{dτ}\right)^2 + \frac{C}{2} \int_0^{h\beta} dτ \int_0^{h\beta} dσ \ g_ω(τ - σ) \ (ρ(τ) - ρ(σ))^2.\tag{7}$$
The resulting Feynman-Jensen inequality gives a solvable upper-bound to the (model) free energy,

$$ F \leq F_0 + \langle S - S_0 \rangle_0, $$

where $F_0$ is the free energy of the trial system and $\langle S - S_0 \rangle_0$ is the expectant difference in the two actions, evaluated with respect to the trial system,

$$ \langle S - S_0 \rangle_0 = \frac{\int D\tau(S - S_0)e^{-S_0[r]/\hbar}}{\int D\tau e^{-S_0[r]/\hbar}}. $$

The process is variational, in that the C (a harmonic coupling term) and $w$ (which controls the exponential decay rate of the interaction in imaginary-time) parameters are varied to minimise the RHS of Eqn. (8), giving the lowest upper-bound to the free energy. Diagrammatic Monte-Carlo shows that this method approaches the true energy across a wide range of coupling parameters\[^3\]\[^13\]\[^28\].

### B. The FHIP mobility

Feynman-Hellwarth-Iddings-Platzman\[^2\] (FHIP) derive an expression for the linear response of the Fröhlich polaron to a weak, spatially uniform, time-varying electric field $E(t) = E_0 \exp(i\Omega t)$, where $\Omega$ is the angular frequency of the field. The field induces a current due to the movement of the electron,

$$ j(\Omega) = \frac{\mathcal{E}(\Omega)}{z(\Omega)} = e \frac{d}{dt} \langle r(t) \rangle, $$

where $z(\Omega)$ is the complex impedance function and $\langle r(t) \rangle$ the expectation of the electron position. For sufficiently weak fields (in the linear response regime), the relationship between the impedance and the Fourier transform of the Green’s function $G(t)$ of the polaron is

$$ \int_{-\infty}^{\infty} dt G(t) e^{-i\Omega t} = G(\Omega) = \frac{1}{\Omega z(\Omega)}, $$

where $G(t) = 0$ for $t < 0$.

The electric field $E(t)$ appears as an addition linear term in the Fröhlich Hamiltonian, $-\mathcal{E} \cdot \mathbf{r}$. The expected electron position can be evaluated from the density matrix $\rho(t)$ of the system,

$$ \langle r(t) \rangle = \text{Tr} \{ \rho r(t) \}. $$

Assuming that the system is initially in thermal equilibrium $\rho_0 = \exp(-\beta H)$, the time evolution of the density matrix is evaluated with

$$ i\hbar \frac{\partial \rho}{\partial t} = [H, \rho]. $$

Therefore, the density matrix at some later time $t$ is

$$ \rho(t) = U(t) \rho_0 U^\dagger(t), $$

where the unitary operators $U$ and $U'$ for time evolution are

$$ U(t) = \exp \left\{ -\frac{i}{\hbar} \int_0^t [H(s) - r(s) \cdot \mathbf{E}(s)] \, ds \right\}, $$

$$ U'(t) = \exp \left\{ -\frac{i}{\hbar} \int_0^t [H'(s) - r'(s) \cdot \mathbf{E}'(s)] \, ds \right\}. $$

Here unprimed operators are time-ordered with latest times on the far left, whereas primed operators are oppositely time-ordered with latest times on the far right. (Technically the electric field $E(t)$ is not an operator in need of time-ordering, but it is useful treat $E$ and $E'$ as different arbitrary functions.)

FHIP assumes that the initial state is a product state of the phonon bath and the electron system, where only the phonon oscillators are initially in thermal equilibrium, $\rho_0 \propto \exp (-\hbar \beta \sum_k \omega_k b_k^\dagger b_k)$ at temperature $T = (k_B \beta)^{-1}$. The true system would quickly thermalise to the temperature of the (much larger) phonon bath, but the linear Feynman polaron model cannot since it is entirely harmonic. As shown by Selk\[^29\], it would be more correct to impose that the entire model system starts in thermal equilibrium. This error results in the lack of a ‘$2\beta'$ dependence in FHIP (low-temperature) dc-mobility.

We can formulate $\text{Tr} \{ \rho(t) \}$ as a path integral generating functional

$$ \text{Tr} \{ \rho(t) \} \equiv Z \left[ E(t), E'(t) \right] $$

$$ = \int D\tau(t) D\tau'(t) \exp \left\{ \frac{i}{\hbar} \Phi \left[ r(t), r'(t) \right] + \frac{i}{\hbar} \left( S[r(t), E(t)] - S[r'(t), E'(t)] \right) \right\}, $$

where $S$ is the classical action of the uncoupled electron,

$$ S[r(t), E(t)] = \int_0^t ds \left[ \frac{m^*}{2} \left( \frac{dr(s)}{ds} \right)^2 + E(s) \cdot r(s) \right]. $$

$\Phi \left[ r(t), r'(t) \right]$ is the phase of the influence functional\[^30\]. The influence functional phase for the Fröhlich model $\Phi_F \left[ r(t), r'(t) \right]$ is derived from the model action (Eqn. (5)) and is given by

$$ \Phi_F \left[ r(t), r'(t) \right] = \frac{i (\hbar \omega_0)^2}{2 \sqrt{2 m^*}} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} ds \left[ g_{\omega_0}(t-s) |r(t) - r'(s)|^2 + g_{\omega_0}(t-s) |r'(t) - r(s)|^2 \right] $$

$$ + g_{\omega_0}(t-s) |r'(t) - r'(s)|^2 + g_{\omega_0}(t-s) |r'(t) - r(s)|^2, $$

where $g_{\omega_0}(t)$ is the real-time phonon Green’s function and is given by

$$ g_{\omega_0}(t) = \frac{\cos (\omega_0 (t - i \hbar \beta / 2))}{\sinh (\hbar \omega_0 \beta / 2)}. $$

The double path integral is over closed paths satisfying the boundary condition $r(t) - r'(t) = 0$ as $t \to \pm \infty$. 
The Green’s function $G(t - t')$ is the response to a \( \delta \)-function electric field $E(s) = e\delta(s - t) = E'(s)$. It can be evaluated from the first functional derivative of the generating functional $Z[E(t), E'(t)]$ with respect to $E(t) - E'(t)$. We can formulate the primed and unprimed electric fields as

\[
E(s) = e\delta(s - t) + \eta\delta(s - t'),
\]

\[
E'(s) = e\delta(s - t) - \eta\delta(s - t').
\]

This reduces the generating functional $Z[E(t), E'(t)]$ into a generating function $Z(\epsilon, \eta)$. The Green’s function can then be evaluated from

\[
G(t - t') = -\frac{\hbar^2}{2} \frac{\partial^2 Z(\epsilon, \eta)}{\partial \epsilon \partial \eta} \bigg|_{\epsilon = \eta = 0}.
\]

In FHIP the generating function $Z(\epsilon, \eta)$ is approximated by taking the zeroth ($Z_0$) and first order ($Z_1$) terms from an expansion of the path integral around an exactly solvable harmonic system. This system is described by a quadratic influence functional phase $\Phi_0[r(t), r'(t)]$ that has been derived from the quadratic trial action $S_0$ (Eqn. 17) and is given by

\[
\Phi_0[r(t), r'(t)] = -\frac{iC}{2} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} ds \left[ \frac{g_{\omega_0}(t - s)}{|r(t) - r(s)|^2} \right. \\
- \frac{g_{\omega_0}(t - s)}{|r'(t) - r'(s)|^2} - \left. 2 \frac{g_{\omega_0}(t - s)}{|r'(t) - r(s)|^2} \right],
\]

where $C$ and $w$ are Feynman’s variational parameters. $Z(\epsilon, \eta)$ is then approximated by two terms,

\[
Z(\epsilon, \eta) = \int D\epsilon D\eta e^{i[S(r) - S'(r) + \Phi[r, r']]} \\
\approx \int D\epsilon D\eta e^{i[S(r) - S'(r) + \Phi_0[r, r']]} \\
\times \left[ 1 + \frac{i}{\hbar} (\Phi[r, r'] - \Phi_0[r, r']) \right] \\
\equiv Z_0 + Z_1.
\]

In FHIP and Devreese et al.\[27\] they find that it is more accurate to use the complex impedance function over the complex conductivity $\sigma(\Omega) (= 1/z(\Omega))$ by taking the Taylor expansion of the impedance,

\[
\Omega z(\Omega) = \frac{1}{G(\Omega)} \approx \frac{1}{G_0(\Omega) + G_1(\Omega)} \approx \frac{1}{G_0(\Omega)} - \frac{1}{G_0(\Omega)^2} G_1(\Omega),
\]

where $G_0$ and $G_1$ are the classical and first-order quantum correction response functions obtained from $Z_0$ and $Z_1$ respectively.

This expansion of the impedance gives

\[
z(\Omega) \approx i \left( \Omega - \frac{\chi(\Omega)}{\Omega} \right),
\]

where

\[
\chi(\Omega) = \frac{2\alpha \omega_0^2}{3\sqrt{\pi}} \int_0^\infty dt \left( 1 - e^{it\Omega} \right) \text{Im}\{S(t)\},
\]

is a memory function that contains all the first-order corrections from the electron-phonon interactions (Eqn. (35a) in FHIP).

Here $S(t)$ (Eqn. (35b) in FHIP) is proportional to the dynamic structure factor for the electron and is given by

\[
S(t) = g_{\omega_0}(t) |D(t)|^{-\frac{3}{2}}
\]

where

\[
D(t) = 2 \frac{v^2 - w^2 \sin(\omega_0 t/2) \sin(\omega_0 t - \beta)}{v^3 \sinh(\omega_0 \beta/2)} - i \frac{w^2}{v^2} \omega_0 t \left( 1 - \frac{t}{\beta} \right).
\]

Our $D(t)$ is the same as $D(u)$ in Eqn. (35c) in FHIP. The frequency-dependent mobility $\mu(\Omega)$ is obtained from the impedance by

\[
\mu(\Omega) = \frac{1}{e} \lim_{\Omega \to 0} \frac{\text{Im}\chi(\Omega)}{\Omega},
\]

where the values of the variational parameters $v$ and $w$ are those that minimise the polaron free energy in Eqn. 9. In the limit that the frequency $\Omega \to 0$ gives the FHIP $dc$-mobility,

\[
\mu_{dc}^{-1} = \frac{m^*}{e} \lim_{\Omega \to 0} \frac{\text{Im}\chi(\Omega)}{\Omega},
\]

since $\text{Re}\chi(\Omega) = 0$.

C. Numerical evaluation of the memory function

In summary, the integral for the memory function is

\[
\chi(\Omega) = \frac{2\alpha \omega_0^2}{3\sqrt{\pi}} \int_0^\infty dt \left( 1 - e^{it\Omega} \right) \text{Im}\{S(t)\}
\]

\[
S(t) = \frac{\cos(\omega_0(t - \beta)/2)}{\sinh(h \omega_0 \beta/2)} |D(t)|^{-\frac{3}{2}}
\]

\[
D(t) = 2 \frac{v^2 - w^2 \sin(\omega_0 t/2) \sin(\omega_0 t - \beta)}{v^3 \sinh(\omega_0 \beta/2)} - i \frac{w^2}{v^2} \omega_0 t \left( 1 - \frac{t}{\beta} \right),
\]
free energy. This is the same as Eqns. (35) in FHIP, but in SI units and with an alternative algebra.

Previous work\textsuperscript{[2] [27]}, including our own (see Appendices), made use of the ‘doubly-oscillatory’ contour-integral expansions, especially at low temperatures, opting instead to transform the integrand for a derivation of the expansion that we believe to be better than those in Refs.\textsuperscript{1} [27], but in Appendix B we provide an in-depth derivation and the real component in terms of Bessel and Struve functions (see Appendix C for a derivation of the expansion that we believe to be new).

However, we found that the cost of evaluating these expansions became large at low temperatures, requiring use of arbitrary-precision numerics to slowly reach converged solutions. In Devreese et al.\textsuperscript{[27]}, they found an alternative analytic expansion for the real component, but similarly found it to have poor convergence for all temperatures, opting instead to transform the integrand to one that has better convergence.

Instead of using any of the contour integrals or power-series expansions, we found that directly numerically integrating Eqn. (31) using an adaptive Gaussian-Kronrod quadrature algorithm leads to faster convergence and controlled errors. Asymptotic limits of these contour integral expansions, especially at low temperatures, may still prove useful.

\section{III. “Beyond Quasiparticle” Polaron Mobility}

Mishchenko et al.\textsuperscript{[3]} recently used diagrammatic Monte Carlo (diagMC) calculations to investigate the violation of the so-called “thermal” analogue to the Mott-Ioffe-Regel (MIR) criterion in the Fröhlich polaron model. This “thermal” MIR criterion is perhaps better referred to as the Planckian bound\textsuperscript{[31]} under which a quasiparticle is stable to inelastic scattering. For the quasiparticle to propagate coherently, the inelastic scattering time \( \tau_{\text{inel}} \) must be greater than the “Planckian time” \( \tau_{\text{Pl}} = \hbar/k_B T \). For the polaron mobility \( \mu \), this requires \( \mu \gtrsim \frac{\hbar}{M k_B T} \). This Planckian bound can be reformulated into Mishchenko’s\textsuperscript{[3]} “thermal” MIR criterion for the validity of the Boltzmann kinetic equation, \( \frac{\lambda}{\lambda} >> \lambda \) where \( \lambda \) is the mean free path, and \( \lambda \) the de Broglie wavelength, of the charge carrier.

The anti-adiabatic limit \( (k_B T \ll \hbar \omega_0) \) corresponds to the weak-coupling limit \( (\alpha \ll 1) \), where the perturbative theory result for the mobility is (Eqn. (5) in Ref.\textsuperscript{3})

\begin{equation}
\mu = \frac{e}{2M \alpha \omega_0} e^{\hbar \omega_0/k_B T} = \frac{e}{2m^* \omega_0} \left( \frac{1}{\alpha} - \frac{1}{6} \right) e^{\hbar \omega_0/k_B T}, \quad (k_B T \ll \hbar \omega_0, \alpha \ll 1),
\end{equation}

where \( M = m^*/(1 - \alpha/6) \) is the effective mass renormalisation of the polaron. In the adiabatic regime \( (k_B T \gg \hbar \omega_0) \), the mobility is obtained from the kinetic equation as (Eqn. (6) in Ref.\textsuperscript{3})

\begin{equation}
\mu = \frac{4e \sqrt{\hbar}}{3\sqrt{\pi \alpha M \sqrt{\omega_0 k_B T}}}, \quad (k_B T \gg \hbar \omega_0),
\end{equation}

which is valid even when \( \alpha \) is not small.
Eq. (34) has the same 1/$\sqrt{T}$ dependence as Eqn. (35). As in Fig. 3, there appears to be a delay in the onset of the exponential behaviour for $k_B T < \hbar \omega_0$. Likewise, the MIR criterion is violated over the temperature range $0.2 < k_B T / \hbar \omega_0 < 10$. At high temperatures, the FHIP mobility (Eqn. (29)) has the same 1/$\sqrt{T}$ dependence as Eqn. (35).

In Fig. 3 we compare the temperature dependence of the FHIP polaron mobility with the diagMC polaron mobility (Fig. 3 in Mishchenko et al. [3]) at $\alpha = 6$. The diagMC polaron mobility exhibits non-monotonic behaviour at $\alpha = 6$, with a clear local minimum around $k_B T = \hbar \omega_0$. Here we see similar non-monotonic behaviour in the FHIP mobility with a small local minimum appearing around $k_B T = \hbar \omega_0$. However, compared to the diagMC mobility, the local minimum of the FHIP mobility is shallower. The onset of this minimum in the FHIP mobility begins around $\alpha = 6$, with the minimum deepening at stronger couplings ($\alpha = 8, 10 \& 12$). Similar to the diagMC mobility, the high-temperature limit is recovered after a maximum at $k_B T / \hbar \omega_0 \sim \alpha$ which shifts with larger $\alpha$. The minimum too appears to be $\alpha$-dependent, occurring at $k_B T / \hbar \omega_0 \sim 1$ for $\alpha = 6$ or $k_B T / \hbar \omega_0 \sim 1.5$ for $\alpha = 12$.

In Fig. 4 we compare the temperature and frequency dependence of the FHIP polaron mobility with the diagMC polaron mobility (Fig. 4 in Mishchenko et al. [3]) at $\alpha = 6$ for temperatures $T = 0.5 \omega_0, 1.0 \omega_0, 2.0 \omega_0$. The FHIP mobility, obtained by integrating Eqn. (29), has similar temperature dependence to the diagMC mobility but differs in the frequency response.

The FHIP mobility shows extra peaks where the first peak is blue-shifted compared to the diagMCs single peak. In [27, 32] it is shown that these extra peaks of the FHIP mobility correspond to internal relaxed excited states of the polaron quasiparticle. These internal states correspond to multiple phonon scattering processes. For $k_B T / \hbar \omega_0 = 0.5$, the first peak around $\Omega / \omega_0 \sim 6$ corresponds to one-phonon processes, the peak at $\Omega / \omega_0 \sim 10$ corresponds to two-phonon processes, and so on. This is more clearly seen by analysing the memory function $\chi(\Omega)$ (Eqn. (26)) at zero temperature, which similarly has peaks at $\Omega / \omega_0 = 1 + n \omega_v$ where $n = 0, 1, 2, \ldots$ and $\omega_v$ is one of the Feynman variational parameters (c.f. Fig. 5). These peaks in the memory function corre-
FIG. 3: The FHIP temperature-dependent mobility in the strong-coupling limit, presented as comparison to Mishchenko et al. The dotted line represents the FHIP model, the dashed line represents the modified FHIP model with a stronger coupling (\(\alpha = 10\)). The solid line represents the original FHIP model with \(\alpha = 6\). The error bars indicate the Monte-Carlo sampling error. The diagram shows pronounced non-monotonic behaviour for \(\alpha = 6\) while the FHIP model requires a stronger coupling, though the \(\alpha = 6\) FHIP result is within the Monte-Carlo error bars.

FIG. 4: The FHIP (solid) frequency- and temperature-dependent mobility, presented as comparison to Mishchenko et al. (black dots, with Monte-Carlo sampling error bars). Presented are \(\alpha = 6\) (black, solid), \(\alpha = 8\) (black, dashed), and \(\alpha = 10\) (black, dotted). The diagrammatic Monte-Carlo results (black, dots, with Monte-Carlo sampling error bars) show pronounced non-monotonic behaviour (the ‘hump’ at \(k_B T/\hbar \omega_0 = 8\)) already with \(\alpha = 6\), while the FHIP model requires a stronger coupling, though we note that the \(\alpha = 6\) FHIP result is within the Monte-Carlo error bars.

FIG. 5: The frequency and temperature dependence of the memory function \(\chi\) (Eqn. (36)). The peaks correspond to the Frank-Condon states of the polaron. For zero temperature \(k_B T/\hbar \omega_0 = 0.0\) (red) the variational parameter \(v = 4.67\) such that the peaks occur at \(\omega_0 + nv\omega_0 = \omega_0, 5.67\omega_0, 10.33\omega_0\) etc. At higher temperatures, the peaks shift to higher frequencies due to the temperature dependence of \(v\) that minimises the polaron free energy at a given temperature.

IV. EXTENDING THE FRÖHLICH MODEL

A. Multiple phonon mode electron phonon coupling

In simple cubic polar materials with two atoms in the unit cell, the single triply-degenerate optical phonon branch is split by dielectric coupling into the singly-degenerate longitudinal-optical (LO) mode and doubly-degenerate transverse-optical (TO) modes. Only the longitudinal-optical mode is infrared active, and contributes to the Fröhlich dielectric electron-phonon interaction.

The infrared activity of this mode drives the formation of the polaron. Much of the original literature therefore just refers to the LO mode. In a more complex material the full range of infrared active modes all contribute to the polaron stabilisation, and the infrared activity of monotonically coupled to a fictitious massive particle (c.f. Section (VI)) lacks a dissipative mechanism for the polaron such that the polaron state described by this model does not lose energy and has an infinite lifetime. However, in de Filippis et al., dissipation is included in this model at zero temperature. This attenuates and spreads the harmonic peaks, obscuring the internal polaron transitions, giving closer agreement to the diagMC mobility at zero temperature. We have not used these methods here but they will be investigated in future work to compliment the multiple phonon model action with a more generalised trial action.
these modes is no longer severely restricted by group theory, but are instead best evaluated numerically. The driving force of the infrared activity, however, is slightly obscured by the algebra in Eqn. (3), and instead this electron-phonon coupling seems to emerge from bulk properties of the lattice. The Pekar factor, \( \frac{1}{\epsilon_{\text{optic}}} - \frac{1}{\epsilon_{\text{static}}} \), being particularly opaque.

Rearranging the Pekar factor as

\[
\left( \frac{1}{\epsilon_{\text{optic}}} - \frac{1}{\epsilon_{\text{static}}} \right) = \frac{\epsilon_{\text{ionic}}}{\epsilon_{\text{optic}} \epsilon_{\text{static}}},
\]

(36)

we can now see that the Fröhlich \( \alpha \) is proportional to the ionic dielectric contribution, as would be expected from appreciating that this is the driving force for polaron formation.

The static dielectric constant is the sum of the high-frequency (‘optical’) response of the electronic structure, and the lower frequency vibrational response of the ions, \( \epsilon_{\text{static}} = \epsilon_{\text{optic}} + \epsilon_{\text{ionic}} \). This vibrational contribution is typically calculated \(^{33}\) by summing the infrared activity of the individual harmonic modes as Lorentz oscillators. This infrared activity can be obtained by projecting the Born effective charges along the dynamic matrix (harmonic phonon) eigenvectors. The overall dielectric function across the phonon frequency range can be written as

\[
\epsilon(\Omega) = \epsilon_{\text{optic}} + \sum_{j=1}^{m} \epsilon_j(\Omega) = \epsilon_{\text{optic}} + 4\pi \frac{u}{\Omega_0} \sum_{j=1}^{m} \frac{(U \cdot q) \cdot (U \cdot q)}{\omega_j^2 - \Omega^2}.
\]

(37)

Here \( U \) are the dynamic matrix eigenvectors, \( \Omega \) is the reduced frequency of interest, \( \omega_j \) is the phonon reduced frequency, \( \Omega_0 \) is the unit cell volume, \( q \) are the Born effective charges, \( j \) indexes the \( j \)th phonon branch and \( m \) is the total number of phonon branches.

Considering the isotropic case (and therefore picking up a factor of \( \frac{1}{2} \) for the averaged interaction with a dipole), and expressing the static (zero-frequency) dielectric contribution, in terms of the infrared activity of a mode \( \epsilon_j \) is

\[
\epsilon_j(0) = \frac{4\pi}{\Omega_0} \frac{1}{3} \frac{\kappa^2}{\Omega_j} q^2 / u
\]

(38)

where \( \kappa \) is the infrared activity in the standard unit of the electron charge (\( q \)) squared per atomic mass unit (\( u \)).

This provides a clear route to defining \( \alpha_j \) for individual phonon branches, with the simple constitutive relationship that \( \alpha = \sum_j \alpha_j \).

\[
\alpha_j = \frac{1}{4\pi \epsilon_0} \frac{\epsilon_j}{\epsilon_{\text{optic}} \epsilon_{\text{static}}} \frac{e^2}{\hbar} \left( \frac{m^*}{2\hbar \omega_j} \right)^{\frac{1}{2}}
\]

(39)

This concept of decomposing \( \alpha \) into constituent pieces associated with individual phonon modes is implicit in the effective mode scheme of Hellwarth and Biaggio\(^{22}\), and has also been used by Verdi\(^{34}\), Verbist\(^{35}\) and Devreese et al.\(^{36}\).

### B. Multiple phonon mode path integral

Verbist and Devreese\(^{35}\) proposed an extended Fröhlich model Hamiltonian (Eqn. (1)) with a sum over multiple (\( m \)) phonon branches,

\[
\hat{H} = \frac{p^2}{2m^*} + \sum_{k,j} \hbar \omega_j a^*_k \hat{a}_{k,j} + \sum_{k,j} (V_{k,j} \hat{a}_{k,j} e^{i\mathbf{k} \cdot \mathbf{r}} + V^*_{k,j} \hat{a}^*_k e^{-i\mathbf{k} \cdot \mathbf{r}}).
\]

(40)

Here the index \( j \) indicates the \( j \)th phonon branch. The interaction coefficient is given by,

\[
V_{k,j} = i \frac{2\hbar \omega_j}{|\mathbf{k}|} \left( \sqrt{\frac{\hbar}{2m^* \omega_j \Omega_0}} \right)^{\frac{1}{2}},
\]

(41)

with \( \alpha_j \) as in Eqn. (39).

From this Hamiltonian we provide the following extended model action to use within the Feynman variational theory,

\[
S_j[\mathbf{r}(\tau)] = \frac{m^*}{2} \int_0^{\hbar \beta} d\tau \left( \frac{d\mathbf{r}(\tau)}{d\tau} \right)^2 - \frac{(\hbar \omega_j)^2}{2\sqrt{2m^* \hbar \beta}} \int_0^{\hbar \beta} d\tau \int_0^{\hbar \beta} dr \int_0^{\hbar \beta} ds \ g_{\omega_j}(|\mathbf{r}(\tau) - \mathbf{r}(\sigma)|).
\]

(42)

Here \( g_{\omega_j}(\tau) \) is the imaginary-time phonon Green’s function for a phonon with frequency \( \omega_j \),

\[
g_{\omega_j}(\tau) = \frac{\cosh (\omega_j(\tau - \hbar \beta / 2))}{\sinh (\hbar \omega_j \beta / 2)}.
\]

(43)

This form of action is consistent with Hellwarth and Biaggio’s\(^{22}\) deduction that inclusion of multiple phonon branches gives the interaction term simply as a sum over terms with phonon frequency \( \omega_j \) and coupling \( \alpha_j \) dependencies.

We now choose a suitable trial action to use with the action in Eqn. (42). We use Feynman’s original trial action with two variational parameters, \( C \) and \( w \), which physically represents a particle (the charge carrier) coupled harmonically to a single fictitious particle (the additional mass of the quasi-particle due to interaction with the phonon field) with a strength \( C \) and a frequency \( w \).

Clearly the dynamics of this model cannot be more complex than can be arrived at with the original Feynman theory, though the direct variational optimisation
function and A equations, we derive the phonon mode dependent of \(\bar{\omega}_j\) from the multiple phonon action in Eqn.\(^{(42)}\) presented here with explicit units,

\[
A = \frac{3}{\hbar \beta \omega_0} \left[ \log \left( \frac{w \sinh(\omega_0 \beta/2)}{w \sinh(\omega_0 \beta/2)} \right) \right] - \frac{1}{2} \log(2\pi \hbar \omega_0),
\]

\[(44a)\]

\[
B = \frac{\alpha \omega_0}{\sqrt{\pi}} \int_0^\beta \frac{d\tau}{\tau} g_{\omega_0}(\tau) [D(\tau)]^{-\frac{1}{2}},
\]

\[(44b)\]

\[
C = \frac{3}{4} \frac{v^2 - w^2}{v} \left( \coth \left( \frac{\omega_0 \beta}{2} \right) - \frac{2}{\omega_0 \beta} \right),
\]

\[(44c)\]

to multiple phonon modes, where \(D(\tau)\) is given in Eqn.\(^{(29)}\). Hellwarth and Biaggio’s B is a symmetrised (for ease of computation) version of the equivalent term from Osaka\(^{(18)}\), although here we have unsymmetrised the integral in B to condense the notation. Compared to Osaka, \(B\) and \(C\) are related to the expectation value of the model action \((S)\) and trial action \(\langle S \rangle\), respectively and \(A\) is the free energy derived from the trial partition function \(F_0 = - \log(Z_0)/\beta\). Following the procedure of Osaka\(^{(18)}\), from the multiple phonon action in Eqn.\(^{(42)}\) we derive the phonon mode dependent \(A_j\) and \(C_j\) equations,

\[
A_j = \frac{3}{\hbar \omega_j \beta} \left[ \log \left( \frac{w \sinh(\omega_j \beta/2)}{w \sinh(\omega_j \beta/2)} \right) \right] - \frac{1}{2} \log(2\pi \hbar \omega_j),\]

\[(45a)\]

\[
C_j = \frac{3}{4} \frac{v^2 - w^2}{v} \left( \coth \left( \frac{\omega_j \beta}{2} \right) - \frac{2}{\omega_j \beta} \right).\]

\[(45b)\]

Similarly, we derive a multiple phonon mode extension to Hellwarth and Biaggio’s B expression,

\[
B_j = \frac{\alpha \omega_j}{\sqrt{\pi}} \int_0^\beta \frac{d\tau}{\tau} g_{\omega_j}(\tau) [D_j(\tau)]^{-\frac{1}{2}},\]

\[(46)\]

where,

\[
D_j(\tau) = 2 \frac{v^2 - w^2}{v^3} \sinh(\omega_j \tau/2) \sinh(\omega_j \hbar \beta - \tau/2) + \left( 1 - \frac{v^2 - w^2}{v^2} \right) \tau \omega_j \left( 1 - \frac{\tau}{\hbar \beta} \right).
\]

\[(47)\]

These are similar to Hellwarth and Biaggio’s single mode versions, but with the single effective phonon frequency \(\omega_0\) substituted with the branch dependent phonon frequencies \(\omega_j\). There are \(m\) with index \(j\) phonon branches.

Summing \(A_j\) in Eqn.\(^{(45a)}\), \(B_j\) in Eqn.\(^{(46)}\), and \(C_j\) in Eqn.\(^{(45b)}\), we obtain a generalised variational inequality for the contribution to the free energy of the polaron from the \(j\)th phonon branch with phonon frequency \(\omega_j\) and coupling constant \(\alpha_j\), and 2 variational parameters \(v\) and \(w\),

\[
F(\beta) \leq - \sum_{j=1}^m \hbar \omega_j (A_j + C_j + B_j).\]

\[(48)\]

Here we have taken care to write out the expression explicitly, rather than use ‘polaron’ units. The entire sum on the RHS of Eqn.\(^{(48)}\) must be minimised simultaneously to ensure we obtain a single pair of \(v\) and \(w\) parameters that give the lowest upper-bound for the total model free energy \(F\).

We obtain variational parameters \(v\) and \(w\) that minimise the free energy expression and will be used in evaluating the polaron mobility. When we consider only one phonon branch \((m = 1)\) this simplifies to Hellwarth and Biaggio’s form of Osaka’s free energy. Feynman’s original athermal version can then be obtained by taking the zero-temperature limit \((\beta \to \infty)\).

D. Multiple phonon mode complex mobility

To generalise the frequency-dependent mobility in Eqn.\(^{(29)}\), we follow the same procedure as FHIP, but use our generalised polaron action \(S\) (Eqn.\(^{(42)}\)) and trial action \(\langle S \rangle\) (Eqn.\(^{(7)}\)). The result is a memory function akin to FHIP’s \(\chi\) (Eqn.\(^{(26)}\)) that now includes multiple \((m)\) phonon branches \(j\),

\[
\chi_{\text{multi}}(\Omega) = \sum_{j=1}^m \frac{\alpha_j \omega_j^2}{3 \sqrt{\pi}} \int_0^\infty dt \left[ 1 - e^{i\Omega t} \right] \text{Im} S_j(t).\]

\[(49)\]

Here,

\[
S_j(\Omega) = g_{\omega_j}(t)[D_j(t)]^{-\frac{1}{2}},\]

\[(50)\]

where \(D_j(t)\) is \(D_j(\tau = -it)\) from Eqn.\(^{(47)}\) rotated back to real-time to give a generalised version of \(D(u)\) in Eqn.\(^{(35c)}\) in FHIP,

\[
D_j(t) = 2 \frac{v^2 - w^2}{v^3} \sin(v \omega_j t/2) \sinh(v \omega_j t/2) + \left( 1 - \frac{v^2 - w^2}{v^2} \right) t \omega_j \left( 1 - \frac{t}{\hbar \beta} \right).
\]

\[(51)\]

The new multiple-phonon frequency-dependent mobility \(\mu_{\text{multi}}(\Omega)\) is then obtained from the real and imaginary parts of the generalised \(\chi_{\text{multi}}(\Omega)\) using Eqn.\(^{(26)}\).
### Table I: Parameters of the Feynman polaron model (single effective phonon mode) as used in this work. Relative high frequency ($\varepsilon_{\text{optical}}$) and static ($\varepsilon_{\text{static}}$) dielectric constants are given in units of the permittivity of free space ($\varepsilon_0$). Frequency (f) is in THz. Effective mass ($m^*$) is in units of the bare electron mass.

| Material | $\varepsilon_{\text{optical}}$ | $\varepsilon_{\text{static}}$ | f | $m^*$ |
|----------|------------------|-----------------|---|--------|
| MAPbI$_3$-e | 4.5 | 24.1 | 2.25 | 0.12 |
| MAPbI$_3$-h | 4.5 | 24.1 | 2.25 | 0.15 |

### Table II: Infrared activity of phonon modes in MAPbI$_3$ taken from Ref. [37] scaled to their ground-state polaron value by the multimodal $w = 2.6792$ factor for MAPbI$_3$-e of this work (Table III).

| Material | $\alpha_j$ | $v_w$ | $E_b$ (meV) |
|----------|------------|------|-------------|
| MAPbI$_3$-e | 2.39 | 3.3086 | 2.6634 | -23.0 meV |
| MAPbI$_3$-h | 2.68 | 3.3586 | 2.6165 | -25.9 meV |
| MAPbI$_3$-e | 2.66 | 3.2923 | 2.6792 | -19.5 meV |
| MAPbI$_3$-h | 2.98 | 3.3388 | 2.6349 | -21.9 meV |

### Table III: Athermal 0 K results. Dielectric electron-phonon coupling ($\alpha$), Feynman athermal variational parameters ($v$ and $w$), polaron free energy ($E_b$, meV), dc mobility ($\mu$, cm$^2$V$^{-1}$s$^{-1}$), polaron effective mass ($M$, $m^*$) and Schultz polaron radius ($r_f$, Å) for an effective phonon mode (top rows) and for multiple explicit phonon modes from Table II (bottom rows).

| Material | $\alpha$ | $v$ | $w$ | $F$ (meV) | $\mu$ | $M$ | $r_f$ |
|----------|--------|-----|-----|----------|------|-----|------|
| MAPbI$_3$-e | 2.39 | 19.9 | 17.0 | -35.5 | 136 | 0.37 | 43.6 |
| MAPbI$_3$-h | 2.68 | 20.1 | 16.8 | -43.6 | 94 | 0.43 | 36.9 |
| MAPbI$_3$-e | 2.66 | 35.2 | 32.5 | -42.8 | 160 | 0.18 | 44.1 |

### V. COMPARISON BETWEEN EFFECTIVE-MODE AND MULTIPLE-MODE THEORIES

Having extended the Feynman theory with explicit phonon modes in the model action, we must now try and answer what improvement this makes.

Halide perovskites are relatively new semiconductors of considerable technical interest. They host strongly interacting large polarons due to their unusual mix of light effective mass yet strong dielectric electron-phonon coupling. Recently the coherent charge-carrier dynamics upon photo-excitation are being measured, the Tera-

---

**Figure 6:** Comparison of the polaron free energy as a function of temperature for MAPbI$_3$ with the single effective phonon mode approach (solid) and the explicit multiple phonon mode approach (dashed).
Eqs. (58) and (59) in Ref. [22],

$$\frac{\kappa_{\text{eff}}^2}{\omega_{\text{eff}}^2} = \sum_{j=1}^{m} \kappa_j^2$$

(52a)

$$\kappa_{\text{eff}}^2 = \sum_{j=1}^{m} \kappa_j^2$$

(52b)

that use an effective LO phonon mode frequency $\omega_{\text{eff}}$ and associated infrared oscillator strength $\kappa_{\text{eff}}$ derived from sums over the phonon modes $j$. We apply both of these methods to the 15 solid-state optical phonon branches of MAPbI$_3$, of which the frequencies and infrared activities are shown in Table II.

Using the Hellwarth and Biaggio[22] effective phonon frequency ‘B’ scheme, the effective phonon frequency for MAPbI$_3$ is $\omega_0 = 2.25 \cdot 2\pi$ THz and the Fröhlich alpha for MAPbI$_3$-e is $\alpha = 2.39$ and MAPbI$_3$-h is $\alpha = 2.68$, as in our previous work[23] (values from bulk dielectric constants).

Using Eqn. (59), we calculated the partial Fröhlich alpha $\alpha_j$ parameters for each of the 15 phonon branches in MAPbI$_3$, which are given in Table II. For MAPbI$_3$-e the partial Fröhlich alphas sum to $\alpha = 2.66$ and for MAPbI$_3$-h they sum to $\alpha = 2.98$. These 15 partial alphas $\alpha_j$ and corresponding phonon frequencies $\omega_j$ were then used in the variational principle for the multiple phonon dependent free energy in Eqn. (48). From Eqn. (48), we variationally evaluate a $v$ and $w$ parameter.

Fig. 7 shows the polaron free energy comparison. The explicit multiple phonon mode approach predicts a higher free energy at temperatures $T < 65$K and a lower free energy at temperatures $T > 65$K. See Table III for our athermal results, where we find new multiple-mode estimates for the polaron binding energy $E_b$ (at 0K) for MAPbI$_3$-e as $E_b = -19.52$ meV and MAPbI$_3$-h as $E_b = -21.92$ meV. Also see Table IV for the thermal results at $T = 300$ K, where we find new multiple-mode estimates for the polaron free energy $F$ for MAPbI$_3$-e at 300 K as $F = -42.84$ meV and MAPbI$_3$-h as $F = -50.40$ meV. These are to be compared to our previous results in Ref. [23] which are also provided in Tables III and IV.

Fig. 7 shows the comparison in polaron variational parameters $v$ and $w$. That we have different trends for the polaron free energy and variational $v$ and $w$ parameters, shows that we find quite a different quasi-particle solution from our multiple phonon scheme compared to the single effective frequency scheme.

### B. DC mobility

We calculate the zero-frequency (direct current, dc) electron-polaron mobility $\mu$ in MAPbI$_3$ using the effective phonon mode and explicit multiple phonon mode approaches. Both approaches have the same relationship between the mobility and the memory function (Eqns. (29) and (30)), but the effective mode approach uses the memory function $\chi(\Omega)$ from Eqn. (26) (the FHIP[2] memory function, Eqn. (35) ibid.), whereas the multiple phonon mode approach uses our $\chi_{\text{multi}}(\Omega)$ from Eqn. (49) (with a sum over the phonon modes).

Fig. 8 shows temperatures 0 K to 400 K. In Fig. 9 we see that the multiple mode approach corrects the single effective mode approach by up to 20%, with this correction maximised at $T=140$ K. The multiple mode mobility slowly approaches the single mode mobility towards higher temperatures. We assume the divergence towards zero temperature to be numerical error due to
the ratio of large floating-point numbers as both mobility values diverge to positive infinity.

C. Complex conductivity and impedance

We calculate the complex impedance \( z_{\text{multi}}(\Omega) \) for the polaron in MAPbI\(_3\) using Eq. (25), where the only difference between the effective mode and multiple mode approaches is in the form of the memory function \( \chi_{\text{multi}}(\Omega) \) as described for the polaron mobility above. The complex conductivity \( \sigma_{\text{multi}}(\Omega) \) is the reciprocal of the complex impedance, \( \sigma_{\text{multi}}(\Omega) = 1/z_{\text{multi}}(\Omega) \).

We show in Fig. 10 the real component, and in Fig. 11 the imaginary component, of the complex conductivity for the single effective mode approach (top) and the explicit multiple mode approach (bottom) for temperatures \( T = 0K, 10K, 40K, 80K, 150K, 300K \) and \( 400K \) (starting with the black solid line through to the yellow solid line) and for frequencies \( 0 \leq \Omega \leq 20 \) THz. The vertical dashed red lines show the LO phonon modes of MAPbI\(_3\). The difference between the two approaches is largest at low temperatures \( T = 0K \) and \( 10K \) where the multiple phonon approach has more structure due to the extra phonon modes. At higher temperatures, the structure attenuates and the two approaches show similar frequency dependence of the complex conductivity at \( T = 300K \) and \( 400K \). These features are further reflected in the real and imaginary components of the complex impedance as shown in Fig. 12 and Fig. 13 respectively.

In Fig. 14 we specifically show the real and imaginary components of the complex conductivity at zero temperature \( T = 0K \) over frequencies \( 0 \leq \Omega \leq 5.0 \) THz for both approaches. Again, the vertical dashed red lines show the longitudinal optical (LO) phonon modes of MAPbI\(_3\) used in the calculation and are shown in Table 1. The single effective mode conductivity shows a peak in the real component at frequencies above the effective mode frequency \( \Omega \geq 2.25 \) THz. Whereas, the real component of the multiple mode conductivity shows peaks at frequencies at and above the LO phonon mode frequencies in MAPbI\(_3\). The imaginary components of both approaches show some structure changes at their respective LO phonon mode frequencies, but are harder to dis-
FIG. 11: Imaginary component of the complex conductivity for MAPbI$_3$ for temperatures $T = 0$K, 10K, 40K, 80K, 150K, 300K & 400K starting with the black curve and finishing with the yellow curve. (Top) Single effective phonon mode prediction. (Bottom) Explicit multiple phonon mode prediction. The red vertical dashed lines indicate the frequencies of the phonon modes.

cern at zero temperature. The most prominent modes in MAPbI$_3$ appear at the large electron-phonon coupled modes $\omega_0 = 0.58, 1.00$ and 2.44 THz.

VI. SIMULATED POLARON VIBRATIONAL MODE SPECTRA

The Feynman polaron quasi-particle has a direct mechanistic interpretation. The Lagrangian consists of an effective-mass electron, an additional fictitious particle (mass $M$, in units of the electron effective-mass), coupled by a harmonic restoring force ($k$). This Lagrangian is given by

$$L = \frac{m^*}{2} \dot{r}(t)^2 + \frac{M}{2} \dot{R}(t)^2 - \frac{k}{2} (r(t) - R(t))^2.$$  \hspace{1cm} (53)

The rate of oscillation of this mode is simply $\omega = \sqrt{\frac{k}{M}}$, expressed as a pre-factor to the material phonon frequency. This oscillation describes the coherent exchange of energy between the electron and the phonon-field.
The phonon frequencies are blue-shifted by the electron-phonon coupling. In terms of the variational parameters \( v \) and \( w \), the spring constant is \( k = v^2 - w^2 \) and the fictitious mass is \( M = (v^2 - w^2)/w^2 \).

Following Schultz[40], the size of the polaron is estimated by calculating the root mean square distance between the electron and the fictitious particle, given as

\[
\rho_f = \sqrt{\frac{\langle r - R \rangle^2}{v^2 - w^2}} = \sqrt{\frac{3v}{v^2 - w^2}} \ a_p,
\]

where the polaron radius is in units of characteristic polaron length \( a_p = \sqrt{\hbar/(2m^*\omega_0)} \).

Fig. [15] shows the comparison in the polaron effective mass \( M \) (units of effective electron mass \( m^* \)) and polaron radius \( \rho_f \) (units of characteristic polaron length \( a_p \)) applied to MAPbI\(_3\). At 300 K we find a new estimates of \( M = 0.18 \ m^* \) and \( \rho_f = 0.755 \ a_p = 44.08 \ \text{Å} \), to be compared to \( M = 0.37 \ m^* \) and \( \rho_f = 0.747 \ a_p = 43.62 \ \text{Å} \) (Table IV). Whilst the introduction of multiple phonon modes barely alters the polaron size, we note that it practically halves the polaron effective mass.

The original work of Feynman[1] provides several
FIG. 16: Numeric Feynman variational solution with the original athermal actions. Blue circles are the value for \( w \), red crosses the value for \( v \). Also shown are the asymptotic approximations, as presented in the original paper and summarised (often with typos) in textbooks. The strong \( (v = \frac{4\alpha^2}{\pi} - \frac{1}{2}(2\log(2) - 1) - \frac{3}{4}) \) and weak \( (v = 3(1 + 2\alpha(1 - P(w))/3w)) \) coupling approximations for \( v \) are green lines, where \( C \approx 0.5772 \) is the Euler Mascheroni constant and \( P(w) = 2(w - 1)^2 - 1) / w \approx 0.2761 \) for \( w = 3 \). The weak \( (w = 3) \) and strong \( (w = 1) \) approximations are purple lines.

Asymptotic estimates of this \( w \) parameter. The standard approximations, often reproduced in textbooks, are \( w = 3 \) for small \( \alpha \) coupling, and \( w = 1 \) for large \( \alpha \) coupling. Precise work requires a numeric solution, but these limits inform us that the internal polaron mode, as a function of electron-phonon coupling, starts as a harmonic of \( 3\omega_0 \) and continuously red-shifts to the phonon fundamental frequency \( \omega_0 \). These parameters as a function of \( \alpha \) are shown in Fig. 16. As there does not seem to be a reference in the literature for numeric values of \( w \) (and \( v \)) as a function of \( \alpha \), we provide this in the supplemental information. From these values, and Eqn. [3], the predicted polaron vibrational renormalisation can be calculated for an arbitrary material without recourse to further numeric calculation.

The finite temperature Osaka action is also described by the Lagrangian which describes the free energy of the polaron state and has the simple mechanistic interpretation of the electron at position \( r(t) \) coupled by a spring with force constant \( k \) to a fictitious particle of mass \( M \) at position \( R(t) \). Practically, the finite temperature action gives rise to a set of \( v \) and \( w \) parameters which scale almost linearly in temperature (Fig. 7 or see Fig. 3 in Ref. [23]). Naive interpretation of those values as simple harmonic oscillators would suggest infeasible high-frequency oscillations at room temperature, with a strong (almost linear) temperature dependence. It may be possible to disentangle the entropic contribution in this Lagrangian, so calculate the correct temperature de-

FIG. 17: Simulated MAPbI\(_3\) polaron vibrational spectrum. Data consist of the polaron renormalised vibrational modes (Table II), with frequency linear varied between 0 at the excited band-edge state, to the fully renormalised frequency in the polaron ground state (predicted to lie 19.517 meV below the band-edge). These straight lines are weighted by the infrared activity (from Ref. [37] calculated by projecting Born-effective-charges along the gamma-point vibrational modes. These data are then smoothed with a two dimensional Kernel density estimator, with Gaussian widths of 0.5 THz (horizontal) and 0.5 meV (vertical), to provide a guide to how a noiseless low-temperature measurement is predicted to look with this theory. (Top) constant infrared activity assumed across binding energies. (Bottom) infrared activity assumed to attenuate to zero as higher lying polaron excited states are accessed.
pendence of the polaron vibration.

Each of the individual dielectrically coupled phonon modes will be scaled by this factor. The electron-phonon coupling in the Fröhlich model is linear, and proportional to the infrared activity of the phonon mode. We can therefore simply plot the expected phonon vibrational spectrum from this model, multiplying the phonon frequencies by the scaling factor \( w \), and directly taking the intensity from the infrared activity.

This rate of vibration is for the ground state of the polaron. The polaron binding energies, indicating where this polaron state is relative to the band edges is given in Table III. The states between here and the band edges are a continuum from the fully bound state (where \( k \) is some factor of \( v \) and \( w \)) to a fully unbound state (where \( k = 0 \)). We can expect \( k \) to linearly decrease as a function of polaron excitation, and so the observed polaron vibrational modes will decrease linearly from these ground state values, to zero at the unbound (band edge) state.

As an example to guide experiment interpretation, we simulate a polaron vibrational measurement. We choose the archetype methylammonium-lead-halide perovskite material. The gamma-point phonon frequencies and infrared activities we take from a previous set of density-functional-theory lattice-dynamic calculations.[37]

We plot these modes as a function of energy below the band edge. The spring-coupling constant is varied linearly between zero at the band edge, to the full ground state value (\( w=2.68 \)). This factor scales the vibrational mode.

The resulting finite set of modes and infrared activities are smoothed with a two dimensional Kernel density estimator, with a Gaussian width of 0.5 THz and 0.5 meV. This is intended as a simulation of spectra resolved at low-temperature.

### VII. DISCUSSION

We have shown that the 60 year old FHIP[2] mobility theory reproduces much of the ‘beyond quasiparticle’ behaviour exhibited in the recent diagrammatic Monte-Carlo calculations[3], including violation of the “thermal” Mott-Ioffe-Regel criterion (or Planckian bound[31]) and, non-monotonic temperature dependence.

Additionally, we have extended the Feynman variational approach to the polaron problem to include multiple phonon modes in the effective model action. Compared to Hellwarth and Biaggio’s[22] effective mode method, we see additional structure in the frequency-dependent mobility, which has recently become something that can be directly measured[25] in the Terahertz regime.

#### A. Violation of the Mott-Ioffe-Regel criterion versus Planckian bound

The usual MIR criterion puts bounds on transport coefficients of the Boltzmann equations for quasiparticle mediated transport, where localised wavepackets are formed from superpositions of single-particle Bloch states. Beyond these bounds, the mean free path of a quasiparticle is of order or smaller than its Compton wavelength, where it is no longer possible to form a coherent quasiparticle from superpositions of Bloch states due to the uncertainty in the single-particle state positions.

Violation of the MIR limit is commonly observed in strongly correlated systems at high temperatures and is often used to suggest that transport in these materials is not described by quasiparticle physics. The “thermal” MIR criterion is also a condition on the validity of the Boltzmann description, but is subtly different to the usual MIR criterion as clearly explained by Hartnoll and Mackenzie[31, 41] who refer to it instead as a “Planckian bound”. Whereas the MIR criterion discerns the ability to form coherent particles from the superposition of Bloch states, the Planckian bound describes the ability of quasiparticles to survive inelastic many-body scattering.

Despite this, here we find that the Feynman variational method, a quasiparticle theory, predicts mobilities outside of the Planckian bound, in good agreement with diagMC mobility predictions.

We strongly caution the use of semi-classical mobility theories using Bloch waves as their charge-carrier wavefunction ansatz to model polar materials.

#### B. Comparison of the FHIP and diagMC mobilities and a note on dissipation

In the Feynman variational theory, we see non-monotonic temperature dependence in the mobility. At strong coupling there is a range of temperatures where the temperature exponent of the mobility is negative, which begins around \( T \simeq \hbar \omega_0 \) and ends around some temperature that scales with the Fröhlich coupling parameter \( \alpha \). The latter high temperature limit marks the transition from strongly coupled polaronic excitations to a thermal electron state (Eq. 35), which is reached asymptotically at large temperatures. Compared to the diagMC mobility, we need to go to larger \( \alpha \) parameters (beyond 8) to start to see a ‘ski jump’ rise in mobility with temperature, whereas in diagMC this is seen already at \( \alpha = 6 \). Though we note that our FHIP results lie within the majority of the Monte-Carlo error bars.

While the temperature-dependence of the FHIP mobility agrees well with the diagMC results, the frequency-dependence differs greatly. This has already been investigated[32] and is due to the harmonic nature of the Feynman trial action. The Feynman trial action...
lacks a dissipative mechanism for the polaron, such that the polaron state described by this model does not lose energy and has an infinite lifetime. The spectral function for this model, \( A(\Omega) = -2\text{Im}\chi(\Omega) \) (where \( \chi \) is the memory function), is a series of delta functions. In [22], this is corrected by including additional dissipation processes, whose strength is fixed by an exact sum rule. This was achieved by directly altering the FHIP memory function, such that the resultant spectral function is a series of Gaussian functions. Their resultant frequency-dependent mobility has better agreement with the diagonal MC mobility.

Another alternative approach to include dissipation may be to extend the trial Lagrangian in Eqn. (53) to incorporate dissipation whilst maintaining that the resulting trial path integral still be evaluable[42, 43]. This would also enable the direct inclusion of anharmonic phonons. Applying these generalised trial actions will be the subject of future work.

C. Numerical evaluation of the memory function

Part of evaluating the FHIP mobility requires a numerical integration in the ‘memory function’ given in Eqn. (26). While this is usually done by rotating the contour of the integral (given by Eqs. (32) and (33)) and expanding as a power-series of special functions, we found that it is far more computationally efficient to directly evaluate the original (non-rotated) integral, using standard adaptive Gauss-Quadrature methods. Part of this investigation lead us to derive power-series expansions for the real and imaginary components of the memory function, which we show in the Appendices. The expansion for the imaginary component in terms of Bessel-K functions has been produced before in[27], however we found a new expansion for the real component in terms of Bessel-I and Struve-L functions. While we ultimately did not use these expansions in our numeric results presented here, asymptotic evakayatuib of these forms may be useful for future theoretical analysis or numerical calculations.

D. The FHIP initial product state and low-temperature mobility

In Sec. [1B] we briefly mentioned that in FHIP[21] they assume a nonphysical initial state, which results in an incorrect low-temperature weak-coupling approximation for the dc-mobility with a spurious \( 2\beta' \) appearing in the denominator of the mobility,

\[
\mu_{\text{FHIP}} = \left( \frac{w}{v} \right)^3 \frac{3e}{2m^2} \frac{\exp(\beta)}{2\beta' \alpha} \exp\left( \frac{v^2 - w^2}{w^2 v} \right). \tag{54}
\]

This observation is important for understanding the \( 3/2\beta \) discrepancy between the low temperature FHIP dc-mobility and Kadanoff’s dc-mobility[44] derived from the Boltzmann equation,

\[
\mu_K = \left( \frac{w}{v} \right)^3 \frac{e}{2m^2} \frac{\exp(\beta)}{\alpha} \exp\left( \frac{v^2 - w^2}{w^2 v} \right). \tag{55}
\]

Some have argued that this discrepancy is due to taking the incorrect order of the limits \( \Omega \to 0 \) and \( \alpha \to 0 \[45\]. An alternative form of the low temperature dc-mobility was derived by Los[46–48] and Sels[29]. Their mobility results differs by a factor of 3 from Kadonoff and by a factor of \( 2\beta \) from FHIP,

\[
\mu_L = \left( \frac{w}{v} \right)^3 \frac{3e}{2m^2} \frac{\exp(\beta)}{\alpha} \exp\left( \frac{v^2 - w^2}{w^2 v} \right). \tag{56}
\]

Sels[29] shows that the difference with Kadonoff is because the relaxation time approximation (neglecting the non-vanishing in-scattering term) used by Kadonoff violates particle number conservation, whereas FHIP does not. However, the FHIP approximation relies on a non-physical initial state for Feynman’s polaron model, as mentioned above. Further, Los[47, 48] shows that not using a factorised initial state of the electron-phonon system results in corrections (although small) due to initial correlations being neglected.

In this work we do not use the low-temperature weak-coupling approximate form of the FHIP mobility, instead we perform a direct numerical integration of the integral in the memory function \( \chi \) in Eqn. (31).

E. The multimodal extension to the Feynman variation approach

We compared the free energy and linear response of the polaron evaluated from the Hellwarth and Biaggio[22] effective phonon mode method to our explicit multiple phonon mode method. Applied to the 15 optical solid-state phonon modes in MAPbI\(_3\), we show that our explicit mode method predicts a slightly higher mobility for temperatures 0 K to 400 K, to a maximum of 20 % increase at 100 K. At 300 K we predict electron and hole mobilities of 160 and 112 cm\(^2\)V\(^{-1}\)s\(^{-1}\) respectively. This is to be compared to our previous predictions of 133 and 94 cm\(^2\)V\(^{-1}\)s\(^{-1}\) for one effective phonon mode evaluated using Hellwarth and Biagio’s[22] ‘B scheme’ (see Eqs. (52a) and (52b)) of 2.25 THz, as evaluated in our previous work in Ref. [23].

More importantly, we recover considerable structure in the complex conductivity and impedance functions as individual phonon modes are activated. This theory provides a quantitative quantum-mechanical method to predict the structure we proposed from semi-classical reasoning in[49] (see Figure 10). Towards higher temperatures the effective and explicit methods show the same temperature and frequency dependence - the quantum details are washed out.
F. Future work and outlook

There are many possible extensions of the Feynman polaron approach to increase the accuracy of the approximations, and to more accurately model real systems. As discussed, dissipative processes in the trial action would avoid unphysical failures to thermalise and spurious quantum recurrences, most notable in the frequency dependent mobility. This requires generalising the trial action. Recently Ichmoukhamedov and Tempere\cite{43}, in applying the variational path integral approach to the Bogoliubov-Fröhlich Hamiltonian, extended the trial action to a more general form, and also considered higher-order corrections beyond the Jensen-Feynman inequality. While the higher-order corrections are known to be small for the original Fröhlich model\cite{50, 51}, they may be important for more general electron-phonon interaction Hamiltonians.

Recently Houtpu et al.\cite{52} have extended the Fröhlich model to anharmonic phonon modes. They show that anharmonicity further localises the polaron. As MAPbI$_3$, and other soft polar semiconductors are highly anharmonic, extending the mobility theory of this paper to include anharmonic couplings would be of considerable utility.

Throughout this paper we have restricted ourselves to a single pair of $\nu$ and $\omega$ variational parameters. It is possible to generalise the theory to multiple normal modes in the quasi-particle solution, which allows for richer structure in the mobility theory, and a closer approximation to complex multi mode materials.

The FHIP approach\cite{2} is limited to the linear-response regime where the applied field is considered weakly alternating. The linear-response regime is sufficient for most technical applications, but non-linear effects may be relevant to interpreting pump-probe THz conductivity measurements. The non-linear extensions\cite{53, 54} of FHIP offer a theoretical route to add this in the future.

VIII. ACKNOWLEDGEMENT

We thank Andrey Mishchenko for providing their raw Diagrammatic Monte-Carlo data\cite{3} for co-plotting, and for useful discussions. We thank Sergio Ciuchi and the anonymous PRB reviewer for critically reading an earlier version of this manuscript. B.A.A.M. is supported by an EPSRC Doctoral Training Award (2446070). J.M.F. is supported by a Royal Society University Research Fellowship (URF-R1-191292). This work used the Imperial College Research Computing Service. Via our membership of the UK’s HEC Materials Chemistry Consortium, which is funded by EPSRC (EP/R029431), this work used the ARCHER2 UK National Supercomputing Service (http://www.archer2.ac.uk). Open-source Julia\cite{56} codes implementing these methods are available as a repository on GitHub\cite{57}.

Following Devreese et al. Ref. [27] we derived infinite-power-series expansions of the real and imaginary components of Eqn. [26] (or Eqn. (35) in Ref. [2]) in terms of Bessel and Struve special functions, and hypergeometric functions.

The practical computational implementation of these expansions was made difficult by the very high precision required on the special functions to make the expansions converge. Using arbitrary precision numerics, a partially working implementation was developed, but it was discovered that direct numeric integration of Eqn. [26] could achieve the same result with less computation time and less complex code.

We start by changing the contour of the memory function as done in Ref. [2]. The memory function for the polaron is defined to linear order in Ref. [16] as: \( \Sigma(\Omega) = \chi' (\Omega) / \Omega \), where,

\[ \chi(\Omega) = \int_0^\infty \left[ 1 - e^{i\Omega u} \right] \text{Im}S(u) \, du, \]  

(A1)

is the

\[ S(u) = \frac{2\alpha}{3\sqrt{\pi}} [D(u)]^{-3/2} \left( e^{iu} + \frac{2}{e^{\beta} - 1}\cos(u) \right), \]  

(A2)

and

\[ D(u) = \frac{\omega^2}{\beta \alpha^2} \left\{ a^2 - \beta^2 / 4 - b \cos(vu) \cosh(v\beta/2) + u^2 - i [b \sin(vu) \sinh(v\beta/2) + u\beta] \right\}, \]  

(A3)

with \( R \equiv (\nu^2 - \omega^2) / (\omega^2 \nu) \), \( a^2 = \beta^2 / 4 + R\beta \coth(\beta v/2) \) and \( b = R\beta / \sinh(\beta v/2) \), which are the same as Eqns. (47b) in Ref. [2].

Solving for the real and imaginary parts of \( \Sigma(\Omega) \) gives the real and imaginary parts of \( \chi(\Omega) \),

\[ \text{Re} \chi(\Omega) = \int_0^\infty [1 - \cos(\Omega u)] \text{Im} S(u) \, du, \]  

(A4a)

\[ \text{Im} \chi(\Omega) = \int_0^\infty \sin(\Omega u) \text{Im} S(u) \, du. \]  

(A4b)

As both \( [1 - \cos(\Omega u)] \) and \( \sin(\Omega) \) are real we can take ‘Im’ outside the integral,

\[ \text{Re} \chi(\Omega) = \text{Im} \int_0^\infty [1 - \cos(\Omega u)] S(u) \, du, \]  

(A5a)

\[ \text{Im} \chi(\Omega) = \text{Im} \int_0^\infty \sin(\Omega u) S(u) \, du. \]  

(A5b)

Now we promote \( u \in \mathbb{R} \) to a complex variable \( u = x + iy \in \mathbb{C} \). The integrals then become integrals on the complex plane,

\[ \text{Re} \chi(\Omega) = \text{Im} \int_\Gamma [1 - \cos(\Omega x) \cosh(\Omega y) + i \sin(\Omega x) \sinh(\Omega y)] S(x + iy) \, du, \]  

(A6a)

\[ \text{Im} \chi(\Omega) = \text{Im} \int_\Gamma [\sin(\Omega x) \cosh(\Omega y) + i \cos(\Omega x) \sinh(\Omega y)] S(x + iy) \, du, \]  

(A6b)

where \( \Gamma \) is our contour of integration. To motivate a choice of contour, let’s consider the form of \( D(x + iy) \) and \( S(x + iy) \),

\[ D(x + iy) = \frac{\omega^2}{\beta \alpha^2} \left\{ \left[ a^2 - \beta^2 / 4 - b \cos(\nu x) \cosh(\nu(y - \beta/2)) + x^2 + (y - \beta/2) \right] \right\} \]  

(A7)

\[ + i [b \sin(\nu x) \sinh(\nu(y - \beta/2)) + 2x(y - \beta/2)] \]
Re(u) \hspace{1cm} \Gamma_3 \hspace{1cm} \infty + i \beta/2

Im(u) \hspace{1cm} \Gamma_1 \hspace{1cm} 0

FIG. 18: The complex contour chosen to transform the integral in Eqn. (A1). No singularities lie within the closed contour so the contour integral is zero.

\[ S(x + iy) = \frac{2\alpha}{3\sqrt{\pi}} \frac{\cos(x + iy - \beta/2)}{\sinh(\beta/2) \left| D(x + iy) \right|^2}. \] (A8)

Now we notice that that \( D(x + iy) \) and \( S(x + iy) \) are trivially real when \( y = \beta/2 \). This gives the results,

\[ D(x + i\beta/2) = \frac{w^2}{\beta v^2} \left[ x^2 + a^2 - b \cos(vx) \right] \in \mathbb{R} \] (A9)

\[ S(x + i\beta/2) = \frac{2\alpha}{3\sqrt{\pi}} \frac{\beta^3}{\sinh(\beta/2)} \left( \frac{v}{w} \right)^3 \frac{\cos(x)}{\left| x^2 + a^2 - b \cos(vx) \right|^2} \in \mathbb{R}. \] (A10)

From this, we choose to integrate over the contours \( \Gamma_1 \in (\infty + 0i, 0 + 0i) \rightarrow \Gamma_2 \in [0 + i0, 0 + i\beta/2] \rightarrow \Gamma_3 \in [0 + i\beta/2, \infty + i\beta/2) \rightarrow \Gamma_4 \in (\infty + i\beta/2, \infty + 0i) \) as shown in Fig. [18]. Since the integrands in Eqns. (A6a) and (A6b) are analytic in this region, this closed contour integral will be zero. (There is a pole in \( \text{Im} \ S(x + iy) \) at \( 0 + i0 \), but this is cancelled by the zero of the elementary/trigonometric functions in front of it at this point.) The closing piece of the contour lies at \( x \rightarrow \infty \) and can be neglected as \( S(x + iy) \rightarrow 0 \) in this limit.

Thus, for the real part of \( \chi(\Omega) \) we have,

\[ \int_{0}^{\infty} \left[ 1 - \cos(\Omega x) \right] S(x) \, dx = \int_{0}^{\beta/2} \left[ 1 - \cosh(\Omega y) \right] S(iy) \, d(iy) \]
\[ + \int_{0}^{\infty} \left[ 1 - \cos(\Omega x) \cosh \left( \frac{\Omega \beta}{2} \right) + i \sin(\Omega x) \sinh \left( \frac{\Omega \beta}{2} \right) \right] S \left( x + \frac{i\beta}{2} \right) \, dx, \] (A11)

and for the imaginary part of \( \chi(\Omega) \) we have,

\[ \int_{0}^{\infty} \sin(\Omega x) S(x) \, dx = i \int_{0}^{\beta/2} \sinh(\Omega y) S(iy) \, d(iy) \]
\[ + \int_{0}^{\infty} \left[ \sin(\Omega x) \cosh \left( \frac{\Omega \beta}{2} \right) + i \cos(\Omega x) \sinh \left( \frac{\Omega \beta}{2} \right) \right] S \left( x + \frac{i\beta}{2} \right) \, dx. \] (A12)

We can now see more clearly why we choose to integrate at \( y = \beta/2 \). Since \( S(x + i\beta/2) \) is real, acting ‘Im’ on these integrals will cancel the second integral in the contour integral for \( \text{Im} \chi(\Omega) \) (which is entirely real), and the third integral for both \( \text{Re} \chi(\Omega) \) and \( \text{Im} \chi(\Omega) \) is simplified due to the absence of any cross-terms that would have resulted.
for other values of \( y \) as \( S(x + iy) \) would have been complex. To see that the second integral for \( \text{Im} \chi(\Omega) \) is real, we need to see if \( S(iy) \) is real. First, we look at \( D(iy) \), which is given by,

\[
D(iy) = \frac{w^2}{\beta v^2} \left[ a^2 - \frac{\beta^2}{4} + y(\beta - y) - b \cosh \left( \frac{vy - \beta v}{2} \right) \right] \in \mathbb{R}, \quad (A13)
\]

and then \( S(iy) \) is given by,

\[
S(iy) = \frac{2\alpha}{3\sqrt{\pi}} \frac{\beta^{3/2}}{\sinh(\beta/2)} \left( \frac{v}{w} \right)^3 \frac{\cosh(y - \beta/2)}{[a^2 - \beta^2/4 + y(\beta - y) - b \cosh(v(y - \beta/2))]^{3/2}} \in \mathbb{R}, \quad (A14)
\]

so \( S(iy) \) is indeed real. Since the second integral for \( \text{Im} \chi(\Omega) \) has two complex \( i \)s and \( S(iy) \) is real, the whole integral is entirely real and so it doesn’t contribute to \( \text{Im} \chi(\Omega) \). Unfortunately, \( \text{Re} \chi(\Omega) \) does not simplify as nicely as \( \text{Im} \chi(\Omega) \) because the second integral is imaginary and so is still present after taking only the imaginary parts. Nonetheless, for \( \text{Re} \chi(\Omega) \) we get,

\[
\text{Re} \chi(\Omega) = \text{Im} \int_0^\infty [1 - \cos(\Omega x)] S(x) \, dx
\]

\[
= \frac{2\alpha}{3\sqrt{\pi}} \frac{\beta^{3/2}}{\sinh(\beta/2)} \left( \frac{v}{w} \right)^3 \left\{ \sinh \left( \frac{\Omega \beta}{2} \right) \int_0^\infty \frac{\sin(\Omega x)\cos(x) \, dx}{[x^2 + a^2 - b \cos(\nu x)]^{3/2}} \right\} + \int_0^{\beta/2} \frac{[1 - \cosh(\Omega x)] \cosh(x - \beta/2) \, dx}{[a^2 - \beta^2/4 + x(\beta - x) - b \cosh(v(x - \beta/2))]^{3/2}} \right\}, \quad (A15)
\]

and for \( \text{Im} \chi(\Omega) \) we get,

\[
\text{Im} \chi(\Omega) = \text{Im} \int_0^\infty \sin(\Omega x) S(x) \, dx = \frac{2\alpha}{3\sqrt{\pi}} \frac{\beta^{3/2}}{\sinh(\beta/2)} \left( \frac{v}{w} \right)^3 \int_0^\infty \frac{\cos(\Omega x)\cos(x) \, dx}{[x^2 + a^2 - b \cos(\nu x)]^{3/2}}. \quad (A16)
\]
Appendix B: $\text{Im} \chi$ expansion in Bessel-K functions

In Devreese et al. Ref. [27] the integral in Eqn. [A16] is expanded in an infinite sum of modified Bessel functions of the second-kind.

Here we follow the same procedure, and arrive at the same result, but provide detailed workings.

Specifically, we are interested in solving the integral,

$$
\int_0^\infty \frac{\cos(\Omega x) \cos(x)}{(x^2 + a^2 - b \cos(vx))^3/2} \, dx
$$

We start by noticing that,

$$
\left| \frac{b \cos(vx)}{x^2 + a^2} \right| < 1 \quad \text{if} \ v > 0 \ \text{and} \ \beta > 0,
$$

so we can do a binomial expansion of the denominator,

$$
\int_0^\infty \frac{\cos(\Omega x) \cos(x)}{(x^2 + a^2)^{3/2}} \left[ 1 - \frac{b \cos(vx)}{x^2 + a^2} \right]^{3/2} \, dx = \int_0^\infty dx \frac{\cos(\Omega x) \cos(x)}{(x^2 + a^2)^{3/2}} \sum_{n=0}^{\infty} \left[ \frac{-3/2}{n} \left( -b \right)^n \cos^n(vx) \right] \cos(x)\cos^2(x) dx
$$

where \((-3/2)\) is a binomial coefficient. Next we expand $\cos^n(vx)$ using the power-reduction formula,

$$
\cos^n(vx) = \frac{1}{2^n} \sum_{k=0}^{\left\lfloor \frac{n-1}{2} \right\rfloor} \binom{n}{k} \cos((n-2k)vx) + \frac{1-n\text{mod}2}{2^n} \binom{n}{\frac{n}{2}}
$$

where the second term comes from even $n$ contributions only. Substituting this into our integral gives,

$$
\sum_{n=0}^{\infty} \left( \frac{-3/2}{n} \right) \left( -\frac{b}{2} \right)^n \sum_{k=0}^{\left\lfloor \frac{n-1}{2} \right\rfloor} \binom{n}{k} \int_0^\infty \frac{\cos(\Omega x) \cos(x) \cos((n-2k)vx)}{(x^2 + a^2)^{n+3/2}} \, dx + \left( 1-n\text{mod}2 \right) \frac{n}{2} \int_0^\infty \cos(\Omega x) \cos(x) \cos \left( \frac{n}{2} \right) \frac{1}{(x^2 + a^2)^{n+3/2}} \, dx.
$$

We can now combine the cosines inside of the integrals into sums of single cosines using,

$$
\cos(\Omega x) \cos(x) \cos(vx(n-2k)) = \frac{1}{4} \left\{ \cos(x(\Omega + 1 + v(n-2k))) + \cos(x(\Omega - 1 + v(n-2k))) + \cos(x(\Omega + 1 - v(n-2k))) + \cos(x(\Omega - 1 - v(n-2k))) \right\}
$$

where for brevity we have defined $z_{kA}^n \in \{ \Omega + 1 + v(n-2k), \Omega - 1 + v(n-2k), \Omega + 1 - v(n-2k), \Omega - 1 - v(n-2k) \}$. Likewise,

$$
\cos(\Omega x) \cos(x) = \frac{1}{2} \left\{ \cos(x(\Omega + 1)) + \cos(x(\Omega - 1)) \right\}
$$

where for brevity we have defined $z_2 \in \{ \Omega + 1, \Omega - 1 \}$. Substituting these into our expansion gives,

$$
\sum_{n=0}^{\infty} \left( \frac{-3/2}{n} \right) \left( -\frac{b}{2} \right)^n \sum_{k=0}^{\left\lfloor \frac{n-1}{2} \right\rfloor} \binom{n}{k} \sum_{z_2} \int_0^\infty \frac{\cos(z_{kA}^n(\Omega))}{(x^2 + a^2)^{n+3/2}} \, dx + \left( 1-n\text{mod}2 \right) \frac{n}{2} \sum_{z_2} \int_0^\infty \frac{\cos(z_2(\Omega))}{(x^2 + a^2)^{n+3/2}} \, dx.
$$
We now have a lot of integrals of the form,

\[ \int_0^\infty \frac{\cos(xz)}{(x^2 + a^2)^{n+3/2}} \, dx, \tag{B9} \]

which is an integral representation for modified Bessel functions of the second kind,

\[ \int_0^\infty \frac{\cos(xz) \, dx}{(x^2 + a^2)^{n+3/2}} = \frac{\sqrt{\pi}}{\Gamma(n + 3/2)} K_{n+1}(|z|a) \left| \frac{z}{2a} \right|^{n+1} \equiv B_n(z) \tag{B10} \]

Thus, overall we can expand \( \text{Im} \chi(\Omega) \) in a series of these Bessel functions,

\[ \text{Im} \chi(\Omega) = \frac{2\alpha \beta^2}{3\sqrt{\pi}} \frac{\sinh(\frac{\Omega \beta}{2})}{\sinh(\beta/2)} \left( \frac{v}{w} \right)^3 \sum_{n=0}^\infty \left( -\frac{3}{2} \right) \left( -\frac{b}{2} \right)^n \left[ \sum_{k=0}^{\left\lfloor \frac{n+1}{2} \right\rfloor} \binom{n}{k} \sum_{z_2} B_n(z_2^2(\Omega)) + (1 - n\text{mod}2) \binom{n}{\frac{n}{2}} \sum_{z_2} B_n(z_2^2(\Omega)) \right] \tag{B11} \]

where \( a^2 = \beta^2/4 + R \beta \coth(\beta v/2), \ b = R \beta / \sinh(\beta v/2) \) and \( R = (v^2 - w^2)/(w^2v) \). Also, \( z_{k,4}^n(\Omega) \in \{ \Omega + 1 + v(n - 2k), \Omega - 1 + v(n - 2k), \Omega + 1 - v(n - 2k), \Omega - 1 - v(n - 2k) \} \) and \( z_2(\Omega) \in \{ \Omega + 1, \Omega - 1 \} \).
Appendix C: Reχ expansion in Bessel-I, Struve-L and \(_1F_2\) hypergeometric functions

Motivated by the expansion of Imχ(Ω) in Devreese et al.[27] we provide a similar expansion for Reχ(Ω).

We follow a similar procedure as for Imχ(Ω) and notice that our efforts focus on solving the integrals,

\[
\int_0^\infty \frac{\sin(\Omega x)\cos(x)}{[x^2 + a^2 - b \cos(vx)]^{3/2}} \, dx \quad \text{(C1)}
\]

\[
\int_0^{\beta/2} \frac{[1 - \cosh(\Omega x)] \cosh(x - \beta/2)}{[a^2 - \beta^2/4 + x(\beta - x) - b \cosh(v(x - \beta/2))]^{3/2}} \, dx \quad \text{(C2)}
\]

The first integral is very similar to Eqn. (B1), just with a cosine swapped out for a sine. Following a similar procedure as for Eqn. (B1) gives,

\[
\int_0^\infty \frac{\sin(\Omega x)\cos(x)}{[x^2 + a^2 - b \cos(vx)]^{3/2}} = \sum_{n=0}^\infty \left( -\frac{3}{2} \right) \left( -\frac{1}{2} \right) ^n \left[ \sum_{k=0}^{n-1} \binom{n}{k} \sum_{n=0}^\infty \frac{\sin(xz^2_1)}{[x^2 + a^2]^{n+3/2}} \, dx + (1 - n \mod 2) \binom{n}{2} \sum_{n=0}^\infty \frac{\sin(xz^2_1)}{[x^2 + a^2]^{n+3/2}} \, dx \right] ,
\]

where we now look for any special functions for which,

\[
\int_0^\infty \frac{\sin(xz)}{(x^2 + a^2)^{n+3/2}} \, dx
\]

is the integral representation. We found that,

\[
\int_0^\infty \frac{\sin(xz)}{(x^2 + a^2)^{n+3/2}} \, dx = \frac{\sqrt{\pi}}{2} \frac{\Gamma(-\frac{1}{2} - n) \sin(z)}{(2a)^{n+1}} \left[ I_{n+1}(|z|a) - L_{-(n+1)}(|z|a) \right] \quad \text{(C5)}
\]

for \( n \geq 0 \) and \( a > 0 \). Here \( \text{sgn}(x) \) is the signum function, \( I_n(x) \) is the modified Bessel function of the first kind, \( L_n(x) \) is the modified Struve function. Therefore, for \( \text{Re}\chi(\Omega) \) we have,

\[
\text{Re}\chi(\Omega) = \frac{2a\beta^{3/2}}{3\sqrt{\pi}} \frac{\sinh\left(\frac{\Omega b}{2}\right)}{\sinh(\beta/2)} \left( \frac{\beta}{\Omega} \right)^3 \left\{ \sum_{n=0}^\infty \left( -\frac{3}{2} \right) \left( \frac{b}{2} \right) ^n \left[ \sum_{k=0}^{n-1} \binom{n}{k} \sum_{z=0}^\infty I_n(z^2_{1,4}(\Omega)) + (1 - n \mod 2) \binom{n}{2} \sum_{z=2}^\infty I_n(z^2_{1,4}(\Omega)) \right] \right\}
\]

\[
+ \frac{2a}{3\sqrt{\pi}} \frac{\beta^{3/2}}{\sinh(\beta/2)} \left( \frac{\beta}{\Omega} \right)^3 \int_0^{\beta/2} \frac{[1 - \cosh(\Omega x)] \cosh(x - \beta/2)}{[a^2 - \beta^2/4 + x(\beta - x) - b \cosh(v(x - \beta/2))]^{3/2}} \, dx \quad \text{(C6)}
\]

where \( a, b, z_1 \) and \( z_2 \) are the same as before.

To expand the second integral with the hyperbolic integrand is more complicated. We start by doing a change of variables \( x \to (1 - x)\beta/2 \) to transform the denominator into a similar form as before and to change the limits to \([0,1] \),

\[
\int_0^{\beta/2} \frac{[1 - \cosh(\Omega x)] \cosh(x - \beta/2)}{[a^2 - \beta^2/4 + x(\beta - x) - b \cosh(v(x - \beta/2))]^{3/2}} \, dx \rightarrow \frac{\beta}{2} \int_0^1 \frac{[1 - \cosh(\Omega \beta] \cosh(v(x - \beta/2)] \cosh(vx/2) \, dx}{[a^2 - (\beta x/2)^2 - b \cosh(v\beta x/2)]^{3/2}} . \quad \text{(C7)}
\]

Now we see that for \( x \in [0,1] \)

\[
\frac{(v \beta x/2)}{a^2 - (\beta x/2)^2} \leq 1 \quad \text{if } v > 0 \text{ and } \beta > 0
\]

so we can do a binomial expansion of the denominator as before,

\[
\sum_{n=0}^\infty \left( -\frac{3}{2} \right) \left( \frac{2}{\beta} \right) ^{2n+2} (-b)^n \int_0^1 \frac{[1 - \cosh(\Omega \beta [1 - x]/2)] \cosh(vx/2) \cosh^n(vx/2) \, dx}{((2a/\beta - x^2)^{n+3/2}} . \quad \text{(C9)}
\]
Then we do another binomial expansion of the remaining denominator
\[
\sum_{n=0}^{\infty} \left( \frac{-3}{n} \right) \left( \frac{2}{\beta} \right)^{2n+2} (-b)^n \sum_{m=0}^{\infty} \left( \frac{-n-3}{m} \right) (-1)^m \left( \frac{\beta}{2a} \right)^{2n+2m+3} \times \int_0^1 \left[ 1 - \cosh \left( \frac{\Omega \beta [1-x]}{2} \right) \right] \cosh \left( \frac{\beta x}{2} \right) \cosh^n \left( \frac{v \beta x}{2} \right) x^{2m} dx.
\] (C10)

We can then expand the product of hyperbolic cosines in the integrand,
\[
\sum_{n=0}^{\infty} \left( \frac{-3}{n} \right) \left( \frac{2}{\beta} \right)^{2n+2} (-b)^n \sum_{m=0}^{\infty} \left( \frac{-n-3}{m} \right) (-1)^m \left( \frac{\beta}{2a} \right)^{2n+2m+3} \frac{1}{2^n} \\
\times \left\{ \binom{n}{n/2} (1 - n \mod 2) \left[ \int_0^1 \cosh \left( \frac{\Omega \beta z}{2} \right) \frac{dz}{x^{2m}} - \frac{1}{2} \sum_{z_2} \left( \cosh \left( \frac{\Omega \beta}{2} \right) \int_0^1 \cosh \left( \frac{\Omega \beta z}{2} \right) \frac{dz}{x^{2m}} \right) \sinh \left( \frac{\Omega \beta}{2} \right) \int_0^1 \frac{dx}{x^{2m}} \right] \\
+ \sum_{k=0}^{n-1} \binom{n}{k} \left[ \sum_{z_3} \int_0^1 \cosh \left( \frac{\Omega \beta z_4}{2} \right) \frac{dz}{x^{2m}} - \frac{1}{2} \sum_{z_4} \left( \cosh \left( \frac{\Omega \beta}{2} \right) \int_0^1 \cosh \left( \frac{\Omega \beta z_4}{2} \right) \frac{dz}{x^{2m}} \right) \sinh \left( \frac{\Omega \beta}{2} \right) \int_0^1 \frac{dx}{x^{2m}} \right] \right\}
\] (C11)

where \( z_1 = 1, z_2(\Omega) \in \{ \Omega + 1, \Omega - 1 \}, z_{k,A}^n \in \{ 1 + v(n-2k), 1 - v(n-2k) \} \) and \( z_{k,A}^n(\Omega) \in \{ \Omega + 1 + v(n-2k), \Omega - 1 + v(n-2k) \} \).

Now we have two integrals of the forms
\[
\int_0^1 \cosh(zx) x^{2m} dx, \quad \int_0^1 \sinh(zx) x^{2m} dx,
\] (C12)

which are the integral forms of the generalised hypergeometric functions
\[
\int_0^1 \cosh(zx) x^{2m} dx = \int_{1/2}^{m+1/2} \frac{t}{3} \frac{z^2}{4} = \sum_{t=0}^{\infty} \frac{z^{2t}}{(2t+2m+1)(2t)!}, \quad m > -1/2
\] (C13a)
\[
\int_0^1 \sinh(zx) x^{2m} dx = \frac{z}{2m+1} \int_{1/2}^{m+1/2} \frac{t}{3} \frac{z^2}{4} = \sum_{t=0}^{\infty} \frac{z^{2t+1}}{(2t+2m+2)(2t+1)!}, \quad m > -1.
\] (C13b)

For brevity, we will define
\[
F^1_2(z) \equiv \int_{1/2}^{m+1/2} \frac{t}{3} \frac{z^2}{4} = \sum_{t=0}^{\infty} \frac{(\beta z/2)^{2t}}{(2t+2m+1)(2t)!},
\] (C14a)
\[
F^2_2(z) \equiv \frac{\beta z}{4m+4} \int_{1/2}^{m+1/2} \frac{t}{3} \frac{z^2}{4} = \sum_{t=0}^{\infty} \frac{(\beta z/2)^{2t+1}}{(2t+2m+2)(2t+1)!},
\] (C14b)

so that Eqn. (C11) becomes
\[
\sum_{n=0}^{\infty} \left( \frac{-3}{n} \right) \left( \frac{2}{\beta} \right)^{2n+2} (-b)^n \sum_{m=0}^{\infty} \left( \frac{-n-3}{m} \right) (-1)^m \left( \frac{\beta}{2a} \right)^{2n+2m+3} \frac{1}{2^n} \\
\times \left\{ \binom{n}{n/2} (1 - n \mod 2) \left[ F^1_2(z_1) - \frac{1}{2} \sum_{z_2} \left( \cosh \left( \frac{\Omega \beta}{2} \right) F^1_2(z_2) - \sinh \left( \frac{\Omega \beta}{2} \right) F^1_2(z_2) \right] \right\} \\
+ \sum_{k=0}^{n-1} \binom{n}{k} \left[ \sum_{z_3} F^1_2(z_3) - \frac{1}{2} \sum_{z_4} \left( \cosh \left( \frac{\Omega \beta}{2} \right) F^1_2(z_4) - \sinh \left( \frac{\Omega \beta}{2} \right) F^1_2(z_4) \right) \right] \right\}
\] (C15)

which we can reduce further by defining
\[
M^i_{a,b}(z) \equiv \sum_{m=0}^{\infty} \left( \frac{-n-3}{m} \right) (-1)^m a^{2(n+m+1)} \beta^{2m+1} \frac{1}{2^n} F^1_2(z)
\] (C16)
to give
\[
\sum_{n=0}^{\infty} \left( -\frac{3}{2} \right)^n \left( -\frac{b}{2} \right)^n \left\{ \binom{n}{a} (1 - \text{nmod}2) \left[ M_n^c(z_1) - \frac{1}{2} \sum_{z_2} \left( \cosh \left( \frac{\Omega \beta}{2} \right) M_n^s(z_2) - \sinh \left( \frac{\Omega \beta}{2} \right) M_n^t(z_2) \right) \right] \\
+ \sum_{k=0}^{\lfloor \frac{n-1}{2} \rfloor} \binom{n}{k} \sum_{z_3} M_n^c(z_3) - \frac{1}{2} \sum_{z_4} \left( \cosh \left( \frac{\Omega \beta}{2} \right) M_n^s(z_4) - \sinh \left( \frac{\Omega \beta}{2} \right) M_n^t(z_4) \right) \right\}. \tag{C17}
\]

Combining this with the rest of \( \text{Re} \chi(\Omega) \) gives
\[
\text{Re} \chi(\Omega) = \frac{2\alpha \beta^{3/2} v^3}{3\sqrt{\pi} \alpha^3 \sinh(\beta/2)} \sum_{n=0}^{\infty} \left( -\frac{3}{2} \right)^n \left( -\frac{b}{2} \right)^n \\
\times \left\{ \binom{n}{a} (1 - \text{nmod}2) \left[ M_n^c(1) + \frac{1}{2} \sum_{z_2} \left( \sinh \left( \frac{\Omega \beta}{2} \right) [M_n^s(z_2(\Omega)) + J_n(z_2(\Omega))] - \cosh \left( \frac{\Omega \beta}{2} \right) M_n^t(z_2(\Omega)) \right) \right] \\
+ \sum_{k=0}^{\lfloor \frac{n-1}{2} \rfloor} \binom{n}{k} \sum_{z_3} M_n^c(z_3) + \frac{1}{2} \sum_{z_4} \left( \sinh \left( \frac{\Omega \beta}{2} \right) [M_n^s(z_4(\Omega)) + J_n(z_4(\Omega))] - \cosh \left( \frac{\Omega \beta}{2} \right) M_n^t(z_4(\Omega)) \right) \right\}. \tag{C18}
\]

So, altogether we have the expansion for the memory function
\[
\chi(\Omega) = \frac{2\alpha \beta^{3/2} v^3}{3\sqrt{\pi} \alpha^3 \sinh(\beta/2)} \sum_{n=0}^{\infty} \left( -\frac{3}{2} \right)^n \left( -\frac{b}{2} \right)^n \\
\times \left\{ \binom{n}{a} (1 - \text{nmod}2) \left[ M_n^c(1) + \frac{1}{2} \sum_{z_2} \left( \sinh \left( \frac{\Omega \beta}{2} \right) [M_n^s(z_2) + J_n(z_2) + iB_n(z_2)] - \cosh \left( \frac{\Omega \beta}{2} \right) M_n^t(z_2(\Omega)) \right) \right] \\
+ \sum_{k=0}^{\lfloor \frac{n-1}{2} \rfloor} \binom{n}{k} \sum_{z_3} M_n^c(z_3) + \frac{1}{2} \sum_{z_4} \left( \sinh \left( \frac{\Omega \beta}{2} \right) [M_n^s(z_4) + J_n(z_4) + iB_n(z_4)] - \cosh \left( \frac{\Omega \beta}{2} \right) M_n^t(z_4(\Omega)) \right) \right\}. \tag{C19}
\]
