Efficacy of repetitive transcranial magnetic stimulation on chronic migraine: A meta-analysis

Jiugen Zhong, Wanting Lan, Yanqing Feng, Ligen Yu, Rang Xiao, Yingying Shen, Zhi Zou and Xiaohui Hou

Introduction: Migraine is a neurovascular disorder that affects the quality of life of more than 1 billion people worldwide. Repetitive transcranial magnetic stimulation (rTMS) is a neuromodulation tool that uses pulsed magnetic fields to modulate the cerebral cortex. This meta-analysis ascertained the therapeutic or preventive effect of rTMS on chronic migraine.

Methods: We performed a database search of PubMed, Web of Science, Embase, and the Cochrane Library from January 2004 to December 2021. Eligible studies included randomized controlled studies of the analgesic effects of rTMS in patients with chronic migraine.

Results: Eight studies were included. Random effects analysis showed an effect size of $−1.13$ (95% confidence interval (CI): $−1.69$ to $−0.58$) on the frequency of migraine attacks, indicating that rTMS was more effective for decreasing migraine attacks than the sham rTMS.

Conclusions: The meta-analysis revealed that rTMS is an effective approach for reducing migraine attack when the dorsolateral prefrontal cortex was stimulated. However, rTMS may not be suggested as a method to reduce the pain level.

Systematic review registration: http://www.crd.york.ac.uk/PROSPERO/, identifier: CRD42021228344.

KEYWORDS repetitive transcranial magnetic stimulation, rTMS, chronic migraine, efficacy, meta-analysis

Introduction

Migraine is a neurovascular disorder that affects more than 1 billion people worldwide. Its widespread prevalence and associated disabilities have a range of negative and substantial impacts not only on directly affected patients but also their families, colleagues, employers, and society (1), as well as a high medical burden (2). Despite its widespread prevalence, migraine remains under-diagnosed and under-treated (3). In general, to eliminate the exacerbating factors, some interventions were be used, for example, lifestyle management (4, 5) and pharmacological treatment (6, 7). Of note, pharmacological treatment has been shown to be effective for migraine, but there are still large individual differences (3), and may bring side effects such as a rapid and progressive headache worsening following anti-CGRP monoclonal antibodies treatment suspension (8). A pilot randomized trial found that both botulinum toxin-A (BTX-A) and repetitive transcranial magnetic stimulation (rTMS) were well tolerated and...
effectively for chronic migraine prophylaxis (9), however, the side effects of BTX-A need to be carefully considered. Therefore, non-pharmacological treatments could serve as a safer and effective method for the management of migraine are needed.

Non-invasive brain stimulation (NiBS) technology has been regarded as an important innovation in neuropsychiatric diseases and chronic pain (including migraine) in recent years and widely used in clinical settings (10–13). Transcranial magnetic stimulation (TMS), which applied a magnetic field to the surface of the scalp and induces current in the subjacent cortex (14), is an effective and safe approach that has been approved by the FDA for migraine treatment (15, 16). As a NiBS method, TMS can excite or depolarize neurons by a fast alternate magnetic field (17), and electrical changes in the brain are believed to regulate neurotransmitters in the brain (14). TMS may reduce pain by modulating the excitability level (14), as patients with migraine tend to show hyperexcitability of the neurons (18). rTMS is a type of TMS, which can deliver a repeated series of magnetic impulses to the cortex (14). Compared to single or paired-pulse TMS, rTMS shows increasing significance as the plastic effect lasts long after the stimulation (19, 20). Chronic migraine patients may also suffer a higher level of central excitability (21). So, the long-lasting effect of rTMS could be appropriate for chronic migraine sufferers.

Several meta-analyses have demonstrated the effect of TMS, rTMS, and tDCS (22–24) on headache, but no review has focused on the effect of rTMS on chronic migraine. As the main effect of rTMS is to modulate the activation level of the cortex, most of the previous evidence showed that rTMS could be mainly used for migraine prophylaxis (25). However, growing evidence has demonstrated the treatment effect of rTMS on migraine in recent years. For instance, Fierro et al. (26) demonstrated that high frequency TMS stimulation on the motor cortex could significantly decrease the pain level of patients with chronic migraine, while the efficacy of the treatment of rTMS on migraine is still under debate. One reason for the uncertain treatment effect could be the different stimulation site. Some studies have shown that stimulation in the motor cortex could reduce pain (27, 28), while others have demonstrated that stimulation on the left dorsal prefrontal cortex (LDPFC) could decrease the frequency of headache attacks (29, 30). However, no evidence has demonstrated the effect of stimulating different sites on patients with chronic migraine.

Therefore, this meta-analysis explored the effect of rTMS on chronic migraine with or without aura. We first analyzed the treatment and prophylaxis effect of rTMS on chronic migraine indexed by the pain intensity and frequency of headache attacks, respectively. The relationship between the stimulation site and efficacy of rTMS was also analyzed.

Methods

The protocol was registered in the International Prospective Register of Systematic Reviews (https://www.crd.york.ac.uk/PROSPERO) with registration number CRD42021228344.

Literature search

A literature search was conducted for studies published in the past 20 years up to December 25, 2021, of studies indexed in four electronic databases, including PubMed, Embase, Web of Science, and the Cochrane Library. The keywords used for identifying rTMS were “repetitive transcranial magnetic stimulation” and “rTMS,” while the keywords used for identifying migraine were “migraine disorder” and “migraine*.” The language was restricted to English. The detail of searching strategies was provided in Supplementary material.

Inclusion criteria

First, articles from the electronic database were initially screened by title and abstract. Two reviewers (Z.J.G and Z.Z) independently screened the title and abstracts of studies to determine whether they met the selection criteria (Table 1). Any disagreement was solved by consensus or by discussion with the third reviewer (H.X.H). Finally, the full texts were analyzed. The detail inclusion criteria were follows: (1) Human study; (2) Parallel or crossover RCT design; (3) Patients with chronic migraine (with/without aura), diagnosed according the International Classification of Headache Disorders (ICHD, 2nd edition) (31); (4) Types of intervention, including rTMS intervention by single or multiple stimulation; (5) Main outcome indicated that pain level was assessed on a visual analog scale (VAS) or numerical pain rating scale (NPR), and the raw data can be extracted from tables or figures. However, the study was excluded that: (1) Did not meet the inclusion criteria; (2) Published without peer review; (3) Treatment paradigm was outside the published safety guidelines.

Bias risk assessment

The quality of the included studies was examined by S.Y.Y and F.Y.Q using the bias risk assessment standards of the Revman 5.3.5 software. Two levels of low and high risk were used for evaluation. If the method used in this complied with the standard of assessment checklist, the risk was considered low; otherwise, if the method did not comply with that of assessment checklist, the risk was considered high. If no corresponding basis

rTMS, repetitive transcranial magnetic stimulation; NPRS, Numeric Pain Rating Scale; VAS, Visual Analog Scale.

was found in the original text or if it was not reported, it was rated as “unclear.”

Outcome measurement

We considered the outcome measures performed at the end of the follow-up. The primary outcome focused on pain intensity evaluated by VAS or NPRS and frequency of headache attacks (days/month). The VAS and NPRS scale will be uniformly converted to a rating scale of 1–10 if the rating scale is 1–100. To reduce the heterogeneity of the research as much as possible, only the post-treatment results at the 1-month (or 4-week) follow-up were extracted, which was used in most studies, when the research had multiple follow-up time nodes.

Data analysis

Revman 5.3.5 software, which was developed by the Cochrane Collaboration, was used for statistical analyses. This analysis was performed separately by two authors (L.W.T and Y.L.G). Data extraction mainly comprised the sample size (for experiment and control groups), sex, age, area of stimulation, parameters of rTMS application (frequency, duration, interval, pulses times), pain intensity, and frequency of headache attacks (the baseline and following up time). The difference in mean value was calculated by Mean$_{post}$ – Mean$_{pre}$, and for the difference in the standard deviation, we used the following formula: SD = $\sqrt{(SD_{pre}^2 + SD_{post}^2 - 2 \times 0.04 \times SD_{pre} \times SD_{post})}$. The random-effects model was applied and statistically significant heterogeneity was assumed when the P value was $< 0.05$. The quantity $I^2$ described the degree of heterogeneity with values of 25, 50, and 75% considered low, moderate, and high, respectively. To explore the possible cause of heterogeneity among study results, the subgroup analysis was used.

Results

Inclusion and selection of studies for meta-analysis

The search strategies yielded 585 results. After the removal of duplicates, 384 articles were identified, after reading titles and abstracts, case-reports and articles that had non-randomized sham-controlled designs, incomplete outcomes, and small sample sizes ($n < 4$) were excluded. Of these, eight were included in the quantitative analysis, with 199 migraine patients and 180 control patients. The details of the study selection are shown in Figure 1. The characteristics of the demographics of the subjects are shown in Table 2. The included studies were
published between January 01, 2004 and December 25, 2021. The parameters of rTMS application and the main outcomes of each study are shown in Table 3.

Quality of the literature

As shown in Figure 2, in eight studies, only one study by Amin et al. (29) reported the clinical identifier, which was considered a rigorous RCT study. Two articles (30, 33) detailed the random assignment method and were double-blinded (subject and evaluator blind), and four articles used randomization but either did not elaborate on the specific method (25, 27, 28) or the random method was inappropriate (34). One article used a placebo control but did not report whether it was randomized (32). Only one study was high quality, two were medium quality, and the remaining five were low-quality studies.

rTMS protocols

Of the included studies, the parameters of rTMS application were heterogeneous. First, for the area of stimulation, three out of eight studies were stimulated at the left dorsolateral prefrontal cortex (LDLPFC), and four out of eight were stimulated at the primary motor cortex (M1) or vertex. One study by Todorov et al. selected both the LDLPFC and M1 as locations of stimulation. Second, the frequency use in four of eight papers was 10 Hz (30, 32, 33), 5 Hz was applied by Amin et al. (29) and Sahu et al. (34), 15 Hz was applied by Todorov et al. (27), 1 Hz was applied by Teepker et al. (28), and 20 Hz was applied by Brighina et al. (25); a 600–1,200 pulse was applied in these studies. Third, the duration of treatment were 5 sessions delivered in consecutive days in most studies (27–29, 34), 3 sessions and 12 sessions were delivered on alternate days by Misra et al. (32, 33) and Brighina et al. (25), respectively. Ten sessions were delivered on consecutive days in the study by Kumar et al. (30). The sham rTMS protocols is similar to real rTMS.

Long-term analgesic effects of rTMS on migraine

To quantify the rTMS effects on migraine intensity, we performed an overall meta-analysis considering both the LDLPFC and M1 stimulation location. The results showed no significant difference between the real and sham rTMS groups in either LDLPFC or M1 region stimulation. However, moderate heterogeneity existed ($I^2 = 73\%$; $P = 0.31$; SMD: $-0.26$; 95% confidence interval (CI): $-0.77$ to $0.24$, Figure 3A). Additionally, no significant difference was observed after we performed a subgroup analysis on different stimulation locations for LDLPFC ($I^2 = 83\%$; $P = 0.22$; SMD: $-0.53$; 95% CI: $-1.42$ to $0.33$, Figure 3B) nor M1 ($I^2 = 61\%$; $P = 0.95$; SMD: $0.02$; 95% CI: $-0.63$ to $0.67$, Figure 3C).

Prevention effects of rTMS on migraine re-attacks

After analyzing the rTMS effects on the frequency of migraine attacks, the pooled standardized mean difference (SMD) effect showed that real rTMS was significantly more effective for decreasing migraine attacks than the sham rTMS, with a high heterogeneity ($I^2 = 83\%; P < 0.001$; SMD: $-1.13$; 95%CI: $-1.69$ to $-0.58$, Figure 4A). Meanwhile, the results of subgroup analysis showed that the rTMS decreased migraine attack frequency when the stimulation was applied to the LDLPFC ($I^2 = 62\%$; $P = 0.03$; SMD: $-0.13$; 95%CI: $-1.62$ to $-0.64$, Figure 4B). However, there was no effect when the stimulation was applied to the M1 cortex ($I^2 = 92\%; P < 0.001$; SMD: $-1.26$; 95%CI: $-2.68$ to $0.15$, Figure 4C).
| Study                  | Area of stimulation | Parameters (including follow up time) | Main outcome (mean ± SD, E/C) | Sham stimulation parameters | Side effect |

rTMS adverse effects

Of eight studies, four reported no adverse effects (29, 30, 32, 35), three reported some adverse effects, such as sleepiness and mild dizziness (28, 33, 34), and only one study reported headache attack during treatment, the stimulation located on the M1 (27). No serious adverse effects were reported.

Discussion

NiBS technology has been regarded as an important innovation in neuropsychiatric diseases and chronic pain including migraine (13). This meta-analysis aimed to explore the effect of rTMS on chronic migraine in different stimulation sites and evaluate the efficacy in terms of pain intensity and headache frequency. Consistent with previous results, we revealed that rTMS is an effective method in migraine prevention and that both the LDLPFC and motor cortex are effective stimulation sites for prevention. When stimulating either one of the two areas, rTMS showed a benefit in the frequency of headache attacks. Some studies have demonstrated that pain was relieved after stimulation in LDLPFC or the motor cortex. However, a combined estimate of effect size indicates that when the LDLPFC or motor cortex is stimulated, rTMS could not improve the pain intensity of chronic migraine.

Based on the results of this study and previous evidence, rTMS could be a beneficial approach to the prevention of migraine re-attack, and stimulation of the left prefrontal cortex was more effective than the motor area. One of the possible
improving the frequency of headaches (13). Meanwhile, the current fMRI study by Mungoven et al. (38) found that reduced whole scan the dorsolateral prefrontal cortex (DLPFC) connectivity with cortical/subcortical and brainstem regions involved in pain modulation was demonstrated in migraineurs. Furthermore, the functional connection between brain regions that play an important role in regulating pain pathways (39). Therefore, as migraine patients tend to show hyperexcitability of brain cells or cortical dilatation inhibition, rTMS could improve cortical excitability by stimulating the DLPFC and helping to regulate disordered pain neural network connections to prevent migraine.

Previous study has described the effects of rTMS on neurotransmitter systems in rodent (42), but these effects for human being has not been determined until now. In addition to the regulation of the center neural system, another reason by which rTMS improves migraine may be to increase the level of β endorphin (BE) in plasma when stimulated DLPFC. A study revealed that the plasma BE levels of patients with chronic migraine were lower than those in the control group. Three sessions rTMS treatments resulted in remission of migraine and increased plasma BE levels, suggesting that the improved migraine symptoms after rTMS stimulation were associated with increased BE levels (43). However, one of the articles included in this meta-analysis showed that rTMS had no significant effect on improving the frequency of headaches (32). This may be related to the non-double-blinded trial design and the existence of a strong placebo effect. Thus, both the real and sham stimulation groups demonstrated an improvement of the level of BE to reduce the severity and frequency of headaches. So, these results suggested that DLPFC was a key center of pain regulation which may serve as a therapeutic target for migraine.

Another factor that determines the effectiveness of rTMS may depend on the frequency. In this review, high frequency stimulation (≥5 Hz) was used in major studies, except for the study by Teepker et al. (28). In general, high frequency stimulation increases cortical excitability, while low frequency stimulation decreases it (44). This effect seems to contradict with the hyperexcitability of the cortex in migraine patients. Of note, the excitability induced by high-frequency rTMS may be the result of the weakened intracortical or neural network connection inhibition mediated by the gamma-aminobutyric acid (GABA) rather than directly caused by increased excitability (45). The underlying pathophysiological factor of migraine may be low cortical excitability, rather than high excitability (28).

From this perspective, high-frequency stimulation may be a better choice for migraine prevention.

rTMS can be used as a preventive treatment for migraine by affecting neurotransmitters and reducing cortical excitability (46, 47). Meanwhile, rTMS stimulation induces synaptic plasticity through long-term enhancement, and repeated stimulation can induce a response for longer than the stimulation period (14). After 5 days of rTMS stimulation, the duration of the strongest analgesic effect is ~1 month, suggesting that repeated stimulation leads to a longer response and obtains a better effect (27).

In total, this meta-analysis adopted the Cochrane systematic review method for research, it provides a direction for future research and clinical treatment. According to this meta-analysis, we preliminary believe that rTMS is of great significance in the prevention of migraine. However, this study still has the following limitations: (1) The efficacy of the rTMS on chronic migraine was preliminary and inconclusive because of the heterogeneity in study designs of rTMS stimulation (including the frequency of stimulation the number of pulse, pulse intensity, and the number of session); (2) The lack of outcomes homogeneity and long-term real world efficacy data, lead to the results do not provide strong evidence to the public; and (3) The sample size is small because of the non-randomized sham-controlled designs, case-reports, had incomplete outcomes, and small sample size (n < 4) were excluded, thus, only eight studies were eligible; (4) As the diagnose criteria used in some studies (25, 28, 33) recruited was ICHD2, the ICHD3 was not adopted in this manuscript, however, from a rigorous perspective, the ICHD third version should be used more in the future study. Finally, none of the eligible trials in this meta-analysis were multicenter trials, and the global reference is therefore limited. So, further high-quality and multicenter trials are needed for confirmation.

Conclusions

The meta-analysis preliminary revealed that rTMS is an effective approach for reducing migraine re-attack when the DLPFC is stimulated. However, rTMS could not be suggested as a method to reduce the pain level.

Data availability statement
