Received 26 April 2001/Returned for modification 17 July 2001/Accepted 18 September 2001

Postweaning multisystemic wasting syndrome of swine associated with porcine circovirus (PCV) is a recently reported and economically important disease. Simple and reliable diagnostic methods are needed for detecting antibodies to PCV type 2 (PCV2) for monitoring of PCV infection. Here, we report the development of two modified indirect enzyme-linked immunosorbent assays (ELISAs): a PCV2 ELISA based on cell-culture-propagated PCV2 and an ORF2 ELISA based on recombinant major capsid protein. PCV2 and ORF2 ELISA detected antibodies to PCV2 and the capsid protein, respectively, in sera from pigs experimentally infected with PCV2 as early as 14 and 21 days postinoculation (dpi). The kinetics of the antibody response to PCV2 and the major capsid protein were similar. Repeatability tests revealed that the coefficients of variation of positive sera within and between runs for both assays were less than 30%. To validate the assays, PCV2 and ORF2 ELISAs were performed with 783 serum samples of young and adult pigs collected from different herds in the Midwestern United States and compared with an indirect immunofluorescent assay (IIF). Six out of 60 samples collected from nursery and growing pigs in 1987 were positive by both ELISA and IIF. Compared with IIF, the diagnostic sensitivity, specificity, and accuracy of PCV2 and ORF2 ELISAs were similar (>90%). The tests showed no cross-reactivity with antibodies to porcine parvovirus and porcine reproductive and respiratory syndrome virus. There was good agreement between the two ELISAs and between the ELISAs and IIF. The availability of the two ELISAs should accelerate our understanding of the host immune response to PCV2 and facilitate the development of prevention and control strategies by elucidating the ecology of PCV2 within swine populations.

**Porcine circovirus** (PCV) was first identified as a PK-15 cell contaminant (46) and was subsequently classified in the family Circoviridae (28). The PCV virions are spherical, have a diameter of 17 nm, and contain single-stranded closed circular genomic DNA 1.7 kb in size (46). In 1991, a wasting disease of weaned pigs emerged in a herd in Saskatchewan, Canada. In 1995, the disease appeared again with higher incidence and at that time was named postweaning multisystemic wasting syndrome (PMWS) (8, 16).

The PK-15 cell contaminant PCV has been shown to be nonpathogenic in experimental studies (1, 47). However in recent studies, PCV was consistently detected in PMWS cases (2, 10, 36). Further genomic analysis revealed that there are two distinct genotypes of PCV (15, 32, 33, 36); PCV type 1 (PCV1) and PCV2 were designated for the nonpathogenic PCV and PMWS-associated PCV, respectively. Differential reactivity with monoclonal antibodies to either PCV1 or PCV2 revealed that they were antigenically different (2, 4). However, a low level of cross-reactivity exists between the two types since antibodies to PCV1 reacted to a low degree with PCV2 (2).

PMWS is a disease of growing pigs with low morbidity but high case mortality. The most common clinical signs are unthriftiness, dyspnea, and jaundice (16). Histological lesions include lymphohistiocytic to granulomatous inflammation in lung, liver, kidney, and lymphoid tissues as well as lymphoid depletion (8). Experiments showed that dual infection of pigs with PCV2 and porcine parvovirus (PPV) caused severe clinical signs and lesions of PMWS (12), while inoculation with PCV2 alone produced only mild to moderate histological lesions (3, 22, 24). Inoculation with PCV1, PPV, or a combination of both PCV1 and PPV failed to produce clinical signs or lesions resembling PMWS (24). In a more recent study, injection of an immunostimulant into PCV2-infected pigs enhanced replication of PCV2 and induced clinical signs and lesions typical of PMWS (25), confirming the role of PCV2 as an essential cause of PMWS. The occurrence of PMWS has been reported worldwide (7, 9, 10, 20, 23, 36, 38, 39, 42, 43, 49).

The genomic organizations of PCV1 and PCV2 are similar. Both contain two major open reading frames (ORFs): ORF1 and ORF2 (15, 32, 33, 36). ORF1 of PCV1 encodes a putative protein involved in viral replication (31). The predicted proteins from ORF2 of PCV1 and PCV2 are similar in size (15, 33, 36). Recently, we reported that ORF2 of PCV2 encodes a major structural protein of approximately 30 kDa and recombinant ORF2 expressed in insect cells self-assembles to form...
virus-like particles (37). The recombinant ORF2 protein reacted strongly with serum from PCV2-infected swine, suggesting its possible use in diagnostic assays.

The most common diagnostic methods for detecting PCV2 antibodies include indirect immunofluorescent assay (IIF) and immunoperoxidase monolayer assay (IPMA) (2, 4, 10). These techniques require experienced technicians, not only for the preparation of infected cells but also for accurate interpretation of the staining reactions. Additionally, examination of IIF and IPMA plates is tedious and time-consuming. Enzyme-linked immunosorbent assay (ELISA) can be automated, hence decreasing the potential bias that may occur with the interpretation of IIF or IPMA results. Recently, an indirect competitive ELISA (cELISA) with high sensitivity and specificity utilizing monoclonal antibodies to PCV2 was reported (48). Here, we describe the development of two modified ELISA systems: a PCV2-infected cell antigen-based ELISA and a recombinant ORF2-based ELISA. The diagnostic sensitivity (DSN) and diagnostic specificity (DSP) of both assays in comparison with IIF are reported.

MATERIALS AND METHODS

Cells and viruses. The working stock of PCV2 strain ISU31 (36) was prepared as previously described (37). To prepare antigen for ELISA, 10^6 50% tissue culture infective doses (TCID_{50}) of PCV2 were mixed with 5 x 10^5 cells of freshly trypsinized PK-15 cells (kindly provided by K. M. Lager, National Animal Disease Center, Ames, Iowa). After 1 h of absorption, the infected cells were maintained in culture medium MEM (Gibco BRL, Grand Island, N.Y.) with 10% fetal bovine serum (Gibco BRL) and 1% antibiotic-antimycotic (100 U of penicillin G per ml, 100 μg of streptomycin sulfate per ml, and 0.025 μg of amphotericin B per ml; Gibco BRL). Mock-infected PK-15 cells were also prepared for control antigen. At 12 h postinoculation (hpi), mock- and PCV2-infected cells were treated with 300 mM D-glucosamine (Gibco BRL) in Hank's balanced salt solution (Gibco BRL) for 30 min at 37°C (47). Cells were harvested at 60 hpi and used for antigen preparation for ELISA.

To prepare plates for IIF, freshly trypsinized PK-15 cells were inoculated with PCV2 at a multiplicity of infection (MOI) of 0.1. One hundred microliters of balanced salt solution (Gibco BRL) for 30 min at 37°C were inoculated into monolayers of Hi-Five insect cells (Invitrogen, Carlsbad, Calif.) at an MOI of 5. The working stock of PCV2 strain ISU31 (36) was prepared by centrifugation at 800 g for 10 min. The supernatant containing wild-type baculovirus (AcMNPV-wt)- or recombinant baculovirus (AcMNPV/ORF2)-infected Hi-Five cells were transferred to a 50-ml centrifuge tube and centrifuged at 800 g for 10 min. The cell pellet was washed three times with cold PBS, pH 7.4, and lyed by incubating on ice for 30 min with 0.5 ml of a lysis buffer containing 50 mM Tris (pH 7.5), 150 mM NaCl, 1% (vol/vol) NP-40, 0.5% (vol/vol) sodium deoxycholate in HEPES, and 0.1% sodium dodecyl sulfate (SDS) (17). Cells were then scraped, transferred into a microcentrifuge tube and incubated on ice for 1 h with periodic mixing on a vortex mixer. The cell suspension was clarified by centrifugation at 10,000 x g for 10 min at 4°C. The supernatant containing either positive antigen (PCV2 Ag) or negative antigen (PK-15 Ag) was dispensed in aliquots and kept at −70°C. The total protein concentration of both antigens was 0.8 mg/ml as determined by Bio-Rad protein assay.

Antigen preparation. For the PCV2 ELISA, positive and negative antigens were prepared from PCV2-infected and noninfected PK-15 cells, respectively. At 60 hpi, cells in 25-cm² flasks were washed three times with cold PBS, pH 7.4, and lyed by incubating on ice for 30 min with 0.5 ml of a lysis buffer containing 50 mM Tris (pH 7.5), 150 mM NaCl, 1% (vol/vol) NP-40, 0.5% (vol/vol) sodium deoxycholate in HEPES, and 0.1% sodium dodecyl sulfate (SDS) (17). Cells were then scraped, transferred into a microcentrifuge tube and incubated on ice for 1 h with periodic mixing on a vortex mixer. The cell suspension was clarified by centrifugation at 10,000 x g for 10 min at 4°C. The supernatant containing either positive antigen (PCV2 Ag) or negative antigen (PK-15 Ag) was dispensed in aliquots and kept at −70°C. The total protein concentration of both antigens was 0.8 mg/ml as determined by Bio-Rad (Hercules, Calif.) protein assay.

Negative and positive antigens for ORF2 ELISA were partially purified proteins from insect cells infected with wild-type or recombinant baculovirus, respectively. At 72 hpi, wild-type baculovirus (AcMNPV-wt)- or recombinant baculovirus (AcMNPV/ORF2)-infected Hi-Five cells were transferred to a 50-ml centrifuge tube and centrifuged at 800 x g for 10 min. The infected cells were frozen and thawed three times to release viral proteins before clarification by centrifugation at 800 x g for 10 min. The supernatant was diluted in PBS, laid over 6 ml of 40% sucrose in PBS, and centrifuged at 270,000 x g for 1 h. The infranatant containing the positive antigen (ORF2 Ag) was dialyzed against cold PBS, pH 7.4, resuspended with PBS, and frozen at −70°C. The infected cells were frozen and thawed three times to release viral proteins before clarification by centrifugation at 800 x g for 10 min. The supernatant was diluted in PBS, laid over 6 ml of 40% sucrose in PBS, and centrifuged at 270,000 x g for 6 h using a Ti 41 SW rotor (Beckman, Palo Alto, Calif.). The pellet was washed three times with cold PBS before incubation with the lysin buffer (150 μl, original cells from a 75-cm² flask) for 30 min on ice. Subsequently, the viral antigen was clarified by centrifugation at 10,000 x g at 4°C for 10 min. Supernatants containing the positive antigen (ORF2 Ag) and negative antigen (WT Ag) were stored in aliquots at −70°C. Both ORF2 Ag and WT Ag had a protein concentration of 1.4 mg/ml as measured by the Bio-Rad protein assay.

Antigen preparation for indirect ELISA. To coat plates for ELISA, the optimum concentration of antigen was determined by checkerboard titration. Two modified ELISA methods, utilizing antigen prepared from PCV2-infected PK-15 cells or recombinant ORF2 protein, were performed as described previously (6). For the conventional PCV2 ELISA, both positive and negative antigens were diluted 1:200 in a carbonate-bicarbonate coating buffer, pH 9.5 (5). The Immulon 2HB polystyrene microtiter plates (Dynex Technologies Inc., Chantilly, Va.) were coated with positive and negative antigen by adding 100 μl of diluted PCV2 or PK-15 Ag into wells of alternate columns. The coated plate was incubated at 4°C for 36 to 40 h and then stored at −20°C. For the ORF2 ELISA, ORF2 and WT Ag were diluted 1:800 in the carbonate-bicarbonate coating buffer, pH 9.5 (5). The Immulon 2HB polystyrene microtiter plates were coated with 100 μl of diluted ORF2 or WT Ag as described for the PCV2 ELISA.

To perform the PCV2 ELISA on experimentally infected pig sera, the plate was thawed, equilibrated at room temperature, and washed three times with 30-s incubation using PBST washing buffer (0.1 M PBS [pH 7.2] and 0.1% Tween 20). Sera were diluted 1 to 40 in 5% milk diluent (Kirkegaard & Perry Laboratories Inc., Gaithersburg, Md.). One hundred microliters of each diluted serum was incubated with positive and negative antigen at 37°C for 30 min. Excess antibodies were removed by washing five times with PBS buffer using a microplate washer (BioTek Instruments Inc., Winooski, Vt.). Plates were blotted between each wash and gently but firmly tapped and blotted dry after the last wash. An optimum dilution of peroxidase-labeled anti-pig immunoglobulin G (100 μl, Sigma) in 5% milk diluent was added into each well. After incubation at 37°C for 30 min, plates were washed five times. Then, 100 μl of freshly prepared and warmed (37°C) 2,2'-
azino-di-(3-ethylbenzthiazoline-6-sulfonate) (ABST) substrate (Kirkegaard & Perry Laboratories Inc.) was added and incubated for 30 min at 37°C. The enzyme-substrate reaction was stopped by adding equal amount of 1% SDS into each well.

The ORF2 ELISA was performed as described for the PCV2 ELISA except that substrate was allowed to react with peroxidase enzyme for 15 min instead of 30 min before the reaction was stopped by adding an equal volume of 1% SDS.

To determine the optimum dilution to test field sera, 22 field sera representing negative (IIF titer less than 10), weak positive (IIF titer between 10 and 100), and strong positive (IIF titer more than 100) serum samples were diluted twofold from 1:50 to 1:20,480. A correlation between IIF titer and S/P ratio of the corresponding serum was determined using Spearman’s rank correlation method (44), and a regression line was plotted between IIF titer and S/P ratio of the corresponding serum samples representing negative (IIF titer of less than 10), weak positive, and strong positive sera. The PCV2 and ORF2 ELISA procedures for testing the field sera were similar to those described for the experimental sera except for the higher (1:100) dilution of tested serum.

The optimum dilution of conjugates for each assay was determined by checkerd board titration. The dilution that gave the highest COD was selected as the optimum dilution. All serum samples were run in quadruplicate, two on positive antigen and two on negative antigen wells. Positive and negative control sera were included in every plate.

To normalize the data, the COD of each serum sample, referred to as sample COD, was divided by a positive serum control COD and reported as the sample/positive (S/P) ratio. To differentiate between negative, weak positive, and strong positive sera, the S/P ratios ranging from 0.097 to 1.307 for PCV2 ELISA and 0.091 to 2.110 for ORF2 ELISA. IIF was performed on twofold serial dilutions of the selected sera from 1:10 to 1:20,480. A correlation between IIF titer and S/P ratio of the corresponding serum was determined using Spearman’s rank correlation method (44), and a regression line was plotted between IIF titer and S/P ratio of the corresponding serum samples using Microsoft Excel. The level of agreement between PCV2 and ORF2 ELISA was determined by the kappa statistic (44), defined as the proportion of potential agreement of two tests beyond chance. We interpreted the agreement of kappa statistic values between the two tests as follows: 0 to 0.2 = slight, 0.2 to 0.4 = fair, 0.4 to 0.6 = moderate, 0.6 to 0.8 = substantial, and 0.8 to 1.0 = excellent.
RESULTS

IIF results. Results of IIF of field serum samples are summarized in Table 1. Out of 783 field sera tested by IIF, 546 were positive and 238 were negative for PCV antibodies. PCV-positive pigs were detected as early as 1987 in Wisconsin. This was followed by positive samples from pigs in Michigan in 1989 and Illinois in 1992. Out of 568 samples collected in 2000 from different herds in Iowa and Oklahoma, 471 samples were positive for PCV antibodies.

ELISA results on experimental pigs. Sixty-nine samples from pigs experimentally infected with PCV2 or culture media were used to evaluate the feasibility of PCV2 and ORF2 ELISA as diagnostic tools. Twenty-five negative sera were obtained from nine pigs in the sham-inoculated group. An additional 24 IIF-negative serum samples were collected from 13 pigs prior to or 1 week postinfection with PCV2. Twenty IIF-positive serum samples were collected at 14 to 49 dpi from seven CD-CD pigs experimentally infected with PCV2. Both PCV2 and ORF2 ELISAs were able to distinguish the sera that were classified by IIF as negative, weakly positive, and strongly positive for PCV2 antibodies. The distribution of IIF-negative and -positive samples according to S/P ratios of pig experimental sera obtained from both ELISAs is shown in Fig. 1. S/P ratios of sera positive by IIF ranged from 0.0497 to 2.6563 for PCV2 ELISA and from 0.0282 to 1.4062 for ORF2 ELISA. S/P ratios of negative sera ranged from −0.0703 to 0.0938 for PCV2 ELISA and −0.0181 to 0.0627 for ORF2 ELISA.

The mean S/P ratios of sera from the pigs surviving the entire duration of the experiment were plotted over time to determine kinetic curves of antibodies to PCV2 and the major capsid protein by PCV2 and ORF2 ELISA, respectively (Fig. 2). Kinetic plots created from both assays were similar. Antibodies to PCV2 and the capsid protein appeared clearly after 14 dpi. The graphs showed gradual increase in antibody levels to PCV2 over the 49 days after infection. S/P ratios of sera from most pigs experimentally infected with PCV2 were more than 0.2 by all assays at 21 dpi.

ELISA results on field sera. We further validated these assays using field sera. A positive serum that consistently gave a high COD and a negative serum with low COD and background were selected from the experimental pigs and used as positive and negative serum controls, respectively. Usually, this positive control serum had CODs of approximately 0.4 and 0.45 for PCV2 and ORF2 ELISA, respectively.

(i) Evaluation of repeatability. The repeatability test was done by comparing S/P ratios of each field serum sample tested in triplicate in intra-assay (within plate) and interassay (between run) in PCV2 and ORF2 ELISA. The results showed that both assays were repeatable. The intra-assay CV of 14 IIF positive serum samples in PCV2 ELISA ranged from 0.29 to 25.70%, with a median value of 6.30%, while those of ORF2 ELISA it was between 0.34 and 7.47%, whereas for ORF2 ELISA it was between 0.29 to 14.47%, with a median value of 6.19%. The interassay CV for positive serum samples in PCV2 ELISA ranged from 0.0173 to 2.9405, with a median value of 0.0704, whereas for ORF2 ELISA it was between 0.0282 to 1.4062 for ORF2 ELISA.

TABLE 2. Repeatability of PCV2 and ORF2 ELISAs for IIF-negative samples of field pig sera

| Repeatability | PCV2 ELISA | ORF2 ELISA |
|---------------|------------|------------|
| Intra-assay   | 0.0292 ± 0.0041 | 0.0266 ± 0.0101 |
| Interassay    | 0.0173 ± 0.0121 | 0.0107 ± 0.0030 |
|               | 0.0032 ± 0.0047 | 0.0046 ± 0.0047 |
|               | 0.0237 ± 0.0051 | 0.0590 ± 0.0018 |
|               | 0.00125 ± 0.0116 | 0.0506 ± 0.0059 |
|               | 0.00119 ± 0.0184 | 0.0884 ± 0.0146 |
|               | 0.00361 ± 0.0108 | 0.0606 ± 0.0030 |
|               | 0.00150 ± 0.0077 | 0.0253 ± 0.0027 |

TABLE 3. Summary of S/P ratios of IIF-negative and -positive sera in PCV2 or ORF2 ELISAs

| Serum group | Parameter | PCV2 ELISA | ORF2 ELISA |
|-------------|-----------|------------|------------|
| IIF negative | Minimum   | −0.1993    | −0.0852    |
| (n = 237)  | Maximum   | 0.2067     | 0.2096     |
|            | Mean      | 0.0476     | 0.0564     |
|            | SD        | 0.0540     | 0.0411     |
|            | Mean + 2SD| 0.1556     | 0.1385     |
|            | Mean + 3SD| 0.2097     | 0.1795     |

| IIF positive | Minimum | 0.0704 | 0.0335 |
| (n = 546)    | Maximum | 2.9405 | 2.6563 |
|              | Mean    | 0.5088 | 0.7977 |
|              | SD      | 0.4196 | 0.6323 |
of S/P ratios were \(-0.1933\) and \(0.2067\) for IIF-negative sera, respectively, and \(-0.0704\) and \(2.9405\) for IIF-positive sera, respectively. The modified receiver-operator characteristic analysis was used to determine the negative-positive cutoff value. The negative cutoff of 0.125 was selected because it resulted in values of more than 90% for both DSN and DSP. At this cutoff, the sum of false results was lowest, as there were 14 false positives and 49 false negatives. The data from performing the assay at a negative cutoff of 0.125 is summarized in Table 4. When the cutoff was moved to 0.2, the DSP of the assay increased to 99.6% while the DSN decreased to 78.2% compared to IIF. Accordingly, serum samples with S/P ratios equal to 0.125 or less were classified as negative, those with ratios of more than 0.125 to 0.2 were equivocal, and those with ratios of more than 0.2 were positive. A COD of positive serum control of at least 0.4 was also required for the assay to be valid. At the negative and positive cutoff values of 0.125 and 0.2, respectively, 429 samples were positive, 82 samples were equivocal and 272 samples were negative (Table 5).

(iii) ORF2 ELISA. The results of the ORF2 ELISA on IIF-negative and -positive sera are summarized in Table 3. The S/P ratios of samples varied from a minimum of \(-0.0852\) to a maximum of 0.2096 for negative sera and from a minimum of 0.0335 to a maximum of 2.6563 for positive sera. The negative-positive cutoff value of 0.1 gave the least sum of false results compared to IIF, as out of 783 samples, 30 were false negative and 27 were false positive. This resulted in a DSN of 94.5% and a DSP of 88.6%. By increasing the negative-positive cutoff value to 0.12, the DSP increased to 93.2% while the DSN decreased to 90.7%. Consequently, total false results increased to 67 samples compared with IIF; however, both DSN and DSP were greater than 90%. The performance of the assay at the negative cutoff of 0.12 is shown in Table 4. When the cutoff was increased to 0.2, the DSP of the assay increased to 99.6% but the DSN decreased to 79.9%. Under these conditions, samples with S/P ratios equal to 0.12 or less were considered negative, those with ratios of more than 0.12 to 0.2 were considered equivocal, and those with ratios of more than 0.2 were considered positive. In addition, a COD of 0.45 or more for the positive serum control was also required to achieve the specified negative-positive cutoff. For the ORF2 ELISA, 437, 74, and 272 serum samples were considered positive, equivocal, and negative, respectively (Table 5). When the samples classified as equivocal by PCV2 (82 samples) and ORF2 (74 samples) ELISAs were analyzed, 34 sera were similar. Out of 34 samples, 33 samples were IIF positive and 1 sample was IIF negative.

S/P ratios obtained from PCV2 and ORF2 ELISA were also plotted against each other. The results showed that their relationship was linear with high correlation (\(r^2\) of 0.7), and the regression equation was S/P ratio (ORF2) = 1.28 S/P ratio (PCV2) + 0.10. Agreement between PCV2 and ORF2 ELISAs was excellent, with a kappa value of 0.81 (\(P < 0.05\)). When the frequency of IIF-positive and -negative serum samples was plotted against the natural log of S/P ratios obtained from either PCV2 or ORF2 ELISA, two overlapping populations appeared as depicted in Fig. 3. The overlapping area represented the equivocal zone for each assay.

(b) Specificity of ELISA. The specificity of both assays was determined by testing the reactivity of PPV- and PRRSV-positive sera. Thirty-six serum samples positive for antibodies to PPV, with reciprocal hemagglutination inhibition titers ranging from 32 to 16,384, had S/P ratios ranging from \(-0.0063\) to 0.0866, with a mean and SD of 0.0298 ± 0.0319 for PCV2 ELISA and from \(-0.0158\) to 0.0971 with a mean and SD of 0.0308 ± 0.0243 for ORF2 ELISA. Thirty-one serum samples containing antibodies to PRRSV from CD-CD pigs experimentally inoculated with PRRSV were also tested for cross-reactivity by both ELISAs. Their S/P ratios were between \(-0.0629\) and 0.0662 with a mean and SD of \(-0.0037\) ± 0.0252 for PCV2 ELISA and between \(-0.0205\) and 0.0250 with a mean and SD of 0.0057 ± 0.0093 for ORF2 ELISA. The results showed that neither ELISA cross-reacted with either PPV- or PRRSV-positive serum.

Correlation between IIF titer and S/P ratio. The correlation between IIF titer and S/P ratio was determined by plotting endpoint IIF titers of 36 serum samples with different levels of antibodies to PCV2 against S/P ratios of the corresponding serum (Fig. 4). The results indicated that the linear relationships between log_{10} titer of IIF and S/P ratio obtained from both PCV2 ELISA (Spearman’s rank correlation = 0.62; \(P < 0.01\)) and ORF2 ELISA (Spearman’s rank correlation = 0.61; \(P < 0.01\)) were similar. There was lower correlation between

---

**Table 4. Performance of PCV2 and ORF2 ELISAs compared with IIF**

| ELISA  | Cutoff (S/P ratio) | Diagnostic value | Predictive value | Accuracy |
|--------|--------------------|------------------|------------------|----------|
|        |                    | % Sensitivity | % Specificity | % Positive | % Negative | % |
| PCV2   | 0.125              | 91.0           | 94.1            | 97.3      | 82.0       | 92.0 |
| ORF2   | 0.12               | 90.7           | 93.2            | 96.9      | 81.3       | 91.4 |

*Comparison was made at cutoff values of 0.125 for PCV2 ELISA and of 0.12 for ORF2 ELISA.

---

**Table 5. Relative comparison between two ELISAs and IIF for detection of antibodies to PCV in field serum samples**

| IIF result | No. of serum samples (%) | Total no. of serum samples |
|------------|--------------------------|---------------------------|
|            | PCV2 ELISA*              |                           |
|            | Positive | Equivocal | Negative | Positive | Equivocal | Negative |
| Positive   | 427 (54.5) | 70 (8.9) | 49 (6.3) | 436 (55.7) | 59 (7.5) | 51 (6.5) | 546 |
| Negative   | 2 (0.3) | 12 (1.5) | 223 (28.5) | 1 (0.1) | 15 (1.9) | 221 (28.2) | 237 |

the sera with low S/P ratios in both ELISA and IIF titers. Conclusively, S/P ratio obtained from either assay could be used to predict IIF titer.

**DISCUSSION**

We have successfully developed and validated two modified indirect ELISAs for the detection of antibodies to PCV2 and its major capsid protein. Both assays could be easily performed and all of the reagents except for the antigens were commercially available. Additionally, extensive purification steps were not necessary for antigen preparation. Every laboratory currently handling PCV2 could easily perform the PCV2 ELISA. However, infection of freshly seeded PK-15 cells with PCV2 at a high MOI (2 or more) was crucial for preparing high quality antigen. Inoculation at a lower MOI of PCV2 decreased the amount of viral protein produced while increasing cellular protein leading to a decrease in COD and sensitivity. Although ORF2 ELISA required the recombinant baculovirus carrying the ORF2 gene of PCV2, there were advantages of ORF2 ELISA over PCV2 ELISA. First, the production of a high-titer baculovirus, either wild type or recombinant, was much easier than the preparation of a high-titer PCV2. Secondly, the recombinant baculovirus produced a much greater amount of PCV2 capsid protein than PCV2 grown in culture. Finally, ORF2 ELISA required a much lower concentration of peroxidase-conjugated anti-swine immunoglobulin G compared with PCV2 ELISA (1:4,000 dilution for ORF2-based ELISA versus 1:1,000 dilution for PCV2-based ELISA), resulting in lower nonspecific background, and the reaction was less dependent on this amplification step.

This is the first published report documenting the existence of PCV2 infection in U.S. swine herds as early as 1987. Six of the 60 serum samples obtained from a herd in Wisconsin in 1987 were positive by all three assays, with IIF titers of more than 100 and S/P ratios ranging from 0.201 to 0.568 for PCV2 ELISA and 0.271 to 0.516 for ORF2 ELISA. This finding was in accordance with several previous reports. PCV2 antigen was detected by immunohistochemistry in pigs necropsied in 1989 in Japan (35). In addition, pooled serum samples from 12 herds in Belgium collected in 1985 (34) and serum samples obtained from sows at a slaughter house in Canada the same year (29) contained antibodies to PCV2.

The results from both ELISAs demonstrated that their DSN and DSP were comparable when IIF was used as the reference method. However, PCV2 and ORF2 ELISAs seemed to be slightly less sensitive than IIF since a considerable number of IIF-positive sera were classified as negative or equivocal by both ELISAs. However, evaluating a newly developed assay by comparison with a widely used assay is not an absolute standard of comparison (21, 44). The relative standard for comparison, in this case the IIF, possesses its own inherent level of sensitivity and specificity (21, 44). In addition, the discrepancy between IIF and ELISA results was possibly due to different epitope recognition. The source of antigen for IIF was fixed cells, while the ELISA antigens were soluble. As expected, both types of antigens contain shared and distinct epitopes which will be recognized by different antibodies.

We were not able to compare our two assays with the previously described cELISA based on monoclonal antibodies (48). Although all three ELISAs were compared against IIF as the reference method, the cutoff dilutions for IIF-positive sera were different. In our study, we defined sera with an IIF titer of 10 or more as positive, while for the cELISA, sera with IIF titers of 50 or more were considered positive.

![FIG. 3. Frequency plots of number of IIF positive (n = 546) and negative (n = 237) samples of field sera and natural log of S/P ratios obtained from either PCV2 (a) or ORF2 (b) ELISA demonstrating two overlapping populations. The number in parentheses is the S/P ratio. The negative and positive cutoffs are 0.125 and 0.2 with a COD of positive serum control of at least 0.4 for the PCV2 ELISA and 0.12 and 0.2 with a COD of positive serum control of at least 0.45 for the ORF2 ELISA. The overlapping area represents an equivocal zone for each assay.](image)

![FIG. 4. Scatter plots of log_{10} IIF titers of 36 serum samples against S/P ratios of the corresponding serum obtained from PCV2 (○) or ORF2 (+) ELISA. The relationships between IIF and S/P ratios of either PCV2 (dashed line) or ORF2 (solid line) ELISAs are linear, with a Spearman’s rank correlation of 0.6.](image)
We felt that it was critical to evaluate the specificity of the ELISAs against PPV and PRRSV as these infections are common in swine and natural coinfections of PCV2 with either PPV or PRRSV have been reported (11, 13, 45). Moreover, experimental coinfection of young pigs with PCV2 and PPV produced clinical signs resembling those observed in field cases of PMWS (3, 12, 22, 24). Our results confirmed that neither PCV2 nor ORF2 ELISA reacted with antibodies to PPV or PRRSV. In addition, we intended to test the specificity of our assays to detect antibodies to PCV1, if PCV1 positive serum was available. We expected that the PCV2 ELISA would detect antibodies to PCV1 and PCV2 since reactivity between PCV1 antibodies and PCV2 antigens has been reported (2, 4). In contrast, we expected that ORF2 ELISA would differentiate between antibodies to PCV1 and PCV2 since antibodies to PCV2 recognized the ORF2 gene product of PCV2 but not that of PCV1 (30). However, at least one shared epitope between ORF2 of PCV2 and PCV2 has been reported (30).

Recently, PCV2 infection in the pig population has been found to be more common than PCV1 infection (13, 26, 27, 29, 40). By PCR, the number of Canadian pigs coinfected with PCV1 and PCV2 was less than the number of those infected with PCV2 alone (26, 27, 40). Thus far, only PCV2 has been detected by in situ hybridization in tissues of pigs with PMWS in the Midwestern United States (S. D. Sorden, unpublished data). Previously, Hines et al. (19) found that sera from 13 swine herds in the United States contained antibodies to the PK-15 contaminant PCV. However, this should be interpreted carefully as antibodies to PCV2 cross-react with PCV1 and PK-15 contaminant PCV. Further testing for reactivity with PCV1 is necessary in regions where PCV1 infections are common.

The ELISA procedures reported here are relatively simple and should be applicable worldwide since homology among PCV2 isolates from different geographic regions is high (37). Both assays have been standardized and validated and thus provide valuable tools for the detection of antibodies to PCV. Due to the semiquantitative nature of ELISA, the application of both assays is not recommended for the detection of antibodies to PCV. Due to the semiquantitative nature of ELISA, the application of both assays is not recommended for the detection of antibodies to PCV.

**ACKNOWLEDGMENTS**

This study was funded in part with a grant from the Iowa State University Research Foundation and a Thai scholarship for Porntippa Nawagtitul. We greatly thank Theresa F. Young and Marsha K. Morgan of Veterinary Medical Research Institute at Iowa State University for technical assistance.
