A B S T R A C T

Few population studies have examined the association between accelerometer-assessed physical activity and dietary behavior. Further, no studies have systematically examined the association between accelerometer-assessed physical activity and flavonoid rich fruits and vegetables in a national sample. As a result, the purpose of this study was to examine the association between objectively measured physical activity and consumption of flavonoid rich fruits and vegetables among a national sample of U.S. adults. Data from the 2003–2006 National Health and Nutrition Examination Survey (NHANES) were used (N = 2949). Physical activity was measured via accelerometry and fruit and vegetable consumption was measured from the NHANES Food Frequency Questionnaire. After adjustments, moderate-to-vigorous physical activity was positively associated (p < 0.05) with apples (β = 0.30), grapes (β = 0.27), strawberries (β = 0.32), oranges (β = 0.35), raw greens (β = 0.19), carrots (β = 0.23), peppers (β = 0.29) and an overall flavonoid index variable (β = 2.34). Future studies employing a longitudinal design are needed to better understand the direction of the observed associations. If future studies do indeed support the possibility that physical activity may help to foster changes in dietary behavior, then this will have strong implications for health behavior interventions, particularly among individuals finding it difficult to change multiple health behaviors concurrently.

Introduction

Emerging research demonstrates that consuming foods rich in flavonoids, such as oranges, grapes, and apples, is associated with improved health, including lower inflammation and reduced incidence of diabetes (Holt et al., 2009; Chun et al., 2008; Zamora-Ros et al., 2013). There is also some encouraging work showing that individuals engaging in higher levels of physical activity tend to eat an ‘overall’ healthier diet than their less active counterparts (Loprinzi et al., 2014; Gillman et al., 2001; Emmons et al., 1994; Eaton et al., 1995; French et al., 1996; Blair et al., 1996; Matthews et al., 1997). However, unlike studies in children and adolescents (Vissers et al., 2013; Jago et al., 2010), these adult studies are limited in the extent that they have exclusively used self-reported physical activity methodology, which is prone to considerable measurement error (Shephard, 2003). Validation studies examining the association between self-report physical activity and some gold-standard (e.g., accelerometry, indirect calorimetry, and doubly labeled water) typically show a poor correlation in the range of 0.3–0.5 (van Poppel et al., 2010; Helmerhorst et al., 2012). Thus, these ‘validated’ self-report questionnaires only account for 9–25% of the variance in the explanatory parameter and are therefore likely to result in considerable misclassification. Further, the few previous studies on this topic did not systematically examine the association between physical activity and foods rich in flavonoids.

As a result, the purpose of this brief study was to examine the association between objectively-measured (accelerometry) physical activity and 15 different food items rich in flavonoids, as identified from the USDA database for the flavonoid content of selected foods. To improve generalizability, data from the 2003–2006 National Health and Nutrition Examination Survey (NHANES) was used. I hypothesize that adults who are more active will consume more food items rich in flavonoids.

Study design and participants

Data from the 2003–2006 National Health and Nutrition Examination Survey (NHANES) were used (only available cycles with accelerometry data at the time of this writing). All procedures for data collection were approved by the National Center for Health Statistics ethics review board, and all participants provided written informed consent prior to data collection. For the present analyses,
2949 adult participants (20–85 yrs) provided data for all study variables.

Assessment of physical activity

2003–2006 NHANES participants were asked to wear an ActiGraph 7164 accelerometer during all activities, except water-based activities and while sleeping. Prior to the participant’s examination, accelerometers were initialized to collect data in one minute time periods. The output of an accelerometer is activity counts, which are proportional to measured acceleration. The ActiGraph 7164 accelerometer measures accelerations in the vertical axis using a piezoelectric plate. The accelerometer output is digitized using an analog-to-digital converter, and once digitized, the signal passes through a digital filter that detects accelerations ranging from 0.05 to 2.00 g in magnitude with frequency responses ranging from 0.25 to 2.5 Hz to filter motion outside normal human movement. The filtered signal is then rectified and summed over a pre-determined epoch period. After the activity count is sorted into an epoch, it is stored in the internal memory and then the integrator is reset to zero.

Activity counts per minute of ≥2020 were used to denote moderate-to-vigorous physical activity (MVPA) intensity (Troiano et al., 2008). Nonwear was defined by a period of a minimum of 60 consecutive minutes of zero activity counts, with the allowance of 1–2 min of activity counts between 0 and 100 (Troiano et al., 2008). For the analyses described here, only those participants with at least 4 days with 10 or more hours per day of monitoring data were included in the analyses (Troiano et al., 2008).

Assessment of flavonoid-rich fruits and vegetables

Based on the National Cancer Institute Diet History Questionnaire (DHQ) that is widely used in nutritional epidemiology research (Subar et al., 2001), participants completed the NHANES Food Frequency Questionnaire (FFQ) (Subar et al., 2006). Briefly, participants were asked to report the proportion of time certain types of foods were eaten. For the present study, which is consistent with other studies (Loprinzi and Mahoney, 2015; Mahoney and Loprinzi, 2014), 15 [solid] fruits and vegetables rich in flavonoids (i.e., apples, grapes, strawberries, oranges, cooked greens, raw greens, carrots, string beans, peas, broccoli, onions, peppers, cucumbers, tomatoes, and lettuce) were identified by using the USDA flavonoid content of foods (USDA, 2007). For each of the 15 food items, response options ranged from 1 to 11, and included never (1), 1–6 times/yr (2), 7–11 times/yr (3), 1 time/month (4), 2–3 times/month (5), 1 time/wk (6), 2 times/wk (7), 3–4 times/wk (8), 5–6 times/wk (9), 1 time/day (10), and 2 or more times/day (11). To create a flavonoid index variable, responses were summed, with higher values indicating more frequent consumption of flavonoid-rich fruits and vegetables. With 15 items, the possible range for the flavonoid index variable is 15–165.

Covariates

Covariates included age (yrs; continuous), gender, race-ethnicity (Mexican American, non-Hispanic white, non-Hispanic black, other), cotinine (ng/dL; continuous), poverty level (range: 0–5), BMI (kg/m²; continuous), and comorbidity index (0–1 + comorbidities). Information about age, gender, and race-ethnicity were obtained from a questionnaire. As a measure of socioeconomic status, poverty-to-income ratio (PIR) was assessed, with a PIR value below 1 considered below the poverty threshold. The PIR is calculated by dividing the family income by the poverty guidelines, which is specific to the family size, year assessed, and state of residence. Serum cotinine was measured as a marker of active smoking status or environmental exposure to tobacco (i.e., passive smoking). Serum cotinine was measured by an isotope dilution-high performance liquid chromatography/atmospheric pressure chemical ionization tandem mass spectrometry. BMI was calculated from measured weight and height (weight in kilograms divided by the square of height in meters). With regard to chronic disease, participants were classified as having 0 or 1+ comorbidities based on self-report of the following chronic diseases/events: arthritis, coronary heart disease, stroke, congestive heart failure, cancer, heart attack, emphysema, chronic bronchitis, asthma, or hypertension.

Data analysis

All statistical analyses (STATA, version 12.0, College Station, TX) accounted for the complex survey design used in NHANES by using survey sample weights, clustering, and primary sampling units. Means and standard errors were calculated for continuous variables and proportions were calculated for categorical variables. To examine the association between MVPA and flavonoid-rich fruits and vegetables (outcome variable), multivariable linear regression analysis was employed. Separate models were computed for each of the fruit and vegetable items. A model using the index variable was also computed. In total, 16 regression models (15 fruit and vegetable items plus the index variable) were computed. Models controlled for age, gender, race-ethnicity, cotinine, poverty level, BMI, and comorbidity index. A p < 0.05 denoted statistical significance for all analyses.

Results

Weighted characteristics of the analyzed sample are shown in Table 1. Participants were, on average, 50 years of age, 56% were female, and 54% were non-Hispanic white.

| Variable | Mean/proportion (95% CI) |
|----------|-------------------------|
| Demographics |
| Age, yr | 49.9 (48.9–50.9) |
| % Female | 56.1 (54.2–58.0) |
| Race-ethnicity, % |
| Mexican American | 7.8 (5.7–9.9) |
| Other Hispanic | 1.9 (1.2–2.6) |
| Non-Hispanic White | 75.7 (71.3–80.1) |
| Non-Hispanic Black | 8.3 (6.0–10.7) |
| Other Race | 6.0 (4.3–7.8) |
| Cotinine, ng/mL | 47.6 (41.4–53.7) |
| Poverty-to-Income Ratio | 3.3 (3.1–3.4) |
| Body Mass Index, kg/m² | 28.1 (27.7–28.5) |
| Comorbidity Index, % |
| 0 Comorbidities | 44.7 (42.4–46.9) |
| 1 + Comorbidities | 55.2 (53.0–57.5) |
| Physical activity |
| MVPA, min/day | 22.3 (21.0–23.5) |
| Diet * |
| Apples | 4.9 (4.7–5.0) |
| Grapes | 4.3 (4.2–4.4) |
| Strawberries | 4.5 (4.4–4.7) |
| Oranges | 4.8 (4.7–5.0) |
| Cooked Greens | 3.5 (3.4–3.7) |
| Raw Greens | 2.9 (2.8–3.1) |
| Carrots | 4.9 (4.8–5.1) |
| String Beans | 5.1 (4.9–5.3) |
| Peas | 4.1 (4.0–4.2) |
| Broccoli | 4.6 (4.4–4.7) |
| Onions | 6.6 (6.5–6.8) |
| Peppers | 4.6 (4.5–4.8) |
| Cucumbers | 4.3 (4.1–4.4) |
| Tomatoes | 6.9 (6.8–7.1) |
| Lettuce | 6.4 (6.2–6.5) |
| Index Variable (sum of each item) | 73.1 (72.0–74.2) |

MVPA = Moderate-to-vigorous physical activity.

* For each of the 15 food items, response options ranged from 1 to 11, and included never (1), 1–6 times/yr (2), 7–11 times/yr (3), 1 time/month (4), 2–3 times/month (5), 1 time/wk (6), 2 times/wk (7), 3–4 times/wk (8), 5–6 times/wk (9), 1 time/day (10), and 2 or more times/day (11).
75.7% were non-Hispanic white, the mean BMI (28.1 kg/m²) was in the ‘overweight’ category, 55.2% had at least one comorbidity, and on average, participants engaged in 22.3 min/day of MVPA. On average, the mean value for the different fruit and vegetable items was less than 5 (index score was 73.1; 73.1/15 items = 4.8). On the scale of 1–11, a value of 5 indicates that the participant consumed that fruit and vegetable 2–3 times a month.

Table 2 reports the weighted multivariable linear regression analyses examining the association between MVPA and each of the flavonoid-rich fruit and vegetable items. For each model, MVPA was expressed as a 30 unit/min change. At the p < 0.05 level, MVPA was associated with apples (β = 0.30), grapes (β = 0.27), strawberries (β = 0.32), oranges (β = 0.35), raw greens (β = 0.19), carrots (β = 0.23), peppers (β = 0.29) and the index variable (β = 2.34). The inclusion of other covariates, including education and total dietary energy intake (kcal/s) from a 24-h recall, did not alter the findings. For example, MVPA remained significantly associated with the index variable after controlling for the original covariates plus education and energy intake (β = 2.34; 95% CI: 0.61–3.87; P = 0.009). Further, when total saturated fat (gm) and total dietary cholesterol (mg) were added to this model, MVPA remained significantly associated with the index variable (β = 2.21; 95% CI: 0.55–3.87; P = 0.01). Even further, when other chronic diseases, such as diabetes status (self-report of physician diagnosis), was added to this last model, results were unchanged (β = 2.21; 95% CI: 0.54–3.88; P = 0.01).

Although it is plausible to suggest an association between MVPA and each of these items, given the multiple comparisons, interpreting these associations while using a more conservative significance threshold may help to minimize a type 1 research error. After applying a Bonferroni-corrected p-value (i.e., 0.003; 0.05/16 regression models = 0.003), MVPA was associated with grapes and strawberries.

### Table 2

| Flavonoid-rich food item (dependent variable) | MVPA (independent variable) | β (95% CI) | P-Value |
|---------------------------------------------|-------------------------------|------------|---------|
| Apples                                      | 0.30                          | 0.06–0.54  | 0.01    |
| Grapes                                      | 0.27                          | 0.10–0.43  | 0.002   |
| Strawberries                                | 0.32                          | 0.17–0.48  | <0.001  |
| Oranges                                     | 0.35                          | 0.12–0.58  | 0.004   |
| Cooked Greens                               | −0.05                         | −0.23–0.12 | 0.52    |
| Raw Greens                                  | 0.19                          | 0.01–0.38  | 0.04    |
| Carrots                                     | 0.23                          | 0.03–0.43  | 0.02    |
| String Beans                                | −0.12                         | −0.32–0.08 | 0.24    |
| Peas                                        | −0.02                         | −0.17–0.13 | 0.77    |
| Broccoli                                    | 0.11                          | −0.10–0.32 | 0.29    |
| Onions                                      | 0.05                          | −0.08–0.19 | 0.43    |
| Peppers                                     | 0.29                          | 0.09–0.48  | 0.006   |
| Cucumbers                                   | 0.13                          | −0.05–0.32 | 0.14    |
| Tomatoes                                    | 0.12                          | −0.05–0.30 | 0.16    |
| Lettuce                                     | 0.14                          | −0.01–0.29 | 0.07    |
| Index Variable (sum of each item)           | 2.34                          | 0.65–4.02  | 0.008   |

16 separate multivariable linear regression models were computed; one for each flavono-

doid-rich food item and the index variable). Each model was adjusted for age, gender, race-ethnicity, cotinine, poverty level, body mass index, and comorbidity index.

MVPA = Moderate-to-vigorous physical activity

* Independent variable, MVPA, expressed as a 30 unit/min change.

The observed association between objectively-measured physical activity and flavonoid rich fruits and vegetables is in support of the few other studies on this topic. For example, Gillman et al. (2001) demonstrated that adults in New England engaging in higher levels of self-reported physical activity, compared to those engaging in less physical activity, consumed greater amount of foods that are considered to be healthy (e.g., fruits, vegetables, fiber, calcium, folate, and vitamins A, C, and E). Similar results were also observed among a different sample of adults in New England (Eaton et al., 1995). Jago et al. (Jago et al., 2005) also showed that, among young adults in the Bogalusa Heart Study (Bogalusa, Louisiana), greater participation in self-reported physical activity was associated with higher fruit intake. Although speculative, the present findings are likely an underestimate of the relationship between MVPA and flavonoid-rich fruit/vegetable intake. In order to assess habitual movement patterns, only those with at least 4 days of 10 + h/day were included in the analysis, and previous work using this data set demonstrates that those with invalid monitoring data tend to be less active and have worse health profiles (Loprinzi et al., 2013), often attenuating associations.

These findings suggest that regular self-reported physical activity participation may be associated with greater consumption of flavonoid-rich fruits and vegetables. The present study extends these findings by employing an objective measure of physical activity and specifically examining flavonoid rich fruits and vegetables that are associated with lower inflammation and reduced incidence of chronic disease (Holt et al., 2009; Chun et al., 2008; Zamora-Ros et al., 2013).

Given the observed cross-sectional association between objectively measured physical activity and flavonoid rich fruits and vegetables, future studies employing a longitudinal design are needed. This will help to better understand the direction of the association between physical activity and fruit and vegetable consumption. It is plausible that consuming a healthier diet may help to facilitate physical activity behavior as individuals who eat ‘healthier’ may have, for example, more energy to engage in physical activity. It is also plausible to suggest that engaging in physical activity may help to foster changes in dietary behavior. For example, physical activity may increase self-efficacy to change other behaviors (e.g., diet) and physical activity has been shown to increase executive functioning, which may help facilitate purposeful, goal-directed behaviors and inhibit goal inconsistent behaviors (Guiney and Machado, 2013).

In summary, the main finding of this study was that objectively-measured physical activity was associated with flavonoid rich fruits and vegetables among this national sample of U.S. adults. Future studies employing a longitudinal design are needed to better understand the direction of the observed association. Such work should also aim to overcome the subjective assessment of dietary behavior in this study. Further, future studies should also aim to assess the association between MVPA and flavonoid rich fruits and vegetables while considering the ratio of flavonoid intake to overall energy intake. Another careful consideration for future studies is to minimize the potential for residual confounding. Although various covariates were included in the present study’s analyses, there is the possibility that unmeasured confounding may be present.

If future studies do indeed support the possibility that physical activity may help to foster changes in dietary behavior, then this will have strong implications for health behavior interventions, particularly among individuals finding it difficult to change multiple health behaviors concurrently.
