We investigate the properties of PbTe doped with a small concentration $x$ of Tl impurities acting as acceptors and described by Anderson impurities with negative onsite correlation energy. We use the numerical renormalization group method to show that the resulting charge Kondo effect naturally accounts for the unusual low temperature and doping dependence of normal state properties, including the self-compensation effect in the carrier density and the nonmagnetic Kondo anomaly in the resistivity. These are found to be in good qualitative agreement with experiment. Our results for the Tl $s$-electron spectral function provide a new interpretation of point contact data.

Introduction.— PbTe is a narrow gap semiconductor with a band gap of 190 meV at zero temperature. Upon doping with Tl impurities a number of striking anomalies appear in the low temperature properties. These anomalies, described below, are currently not well understood. They are believed to be due to the special nature of Tl impurities in PbTe, which have been proposed to act as negative U centers, where $U < 0$ is an attractive onsite Coulomb energy. In compounds, the outer 6s shell of Tl can be empty, singly occupied or doubly occupied. A negative Coulomb correlation results in the nonmagnetic empty and doubly occupied states being lower in energy than the magnetic singly occupied state. Hybridization of the $s$-states with the valence band states of PbTe can then result, via dynamic valence fluctuations, in a (nonmagnetic) charge Kondo (CK) analogue of the conventional spin Kondo effect. This nonmagnetic CK effect has been argued to explain many of the observed properties of Pb$_{1-x}$Tl$_x$Te which would then constitute the first physical realization of this effect.

A remarkable feature of Pb$_{1-x}$Tl$_x$Te is that the low temperature properties depend sensitively on the Tl concentration, with a qualitatively different behavior below and above a critical concentration $x_c \approx 0.3$ % Tl. For example, while Pb$_{1-x}$Tl$_x$Te remains metallic down to the lowest temperatures for $x < x_c$, for $x > x_c$ it becomes superconducting with a transition temperature $T_c(x)$ increasing linearly with $x$ and reaching 1.5 K at $x \approx 1.5$ % Tl. This is surprisingly high given the low carrier density of less than 10$^{20}$ holes/cm$^3$. In addition, measurements of the Hall number $\rho_H = 1/R_H$ indicate that the number of holes grows linearly with $x$ for $x < x_c$, whereas for $x > x_c$, the number of holes remains almost constant: the system exhibits “self-compensation” and the chemical potential is pinned to a value $\mu = \mu^* \approx 220$ meV. Transport measurements also show anomalous behavior at low temperatures: while for $x < x_c$, the residual resistivity, $\rho_0$, is very small and almost constant as a function of $x$, for $x > x_c$, $\rho_0$ increases linearly with $x$. For $x < x_c$, the resistivity, $\rho(T)$, exhibits a positive slope at low temperature, while for $x > x_c$, the slope is negative and a Kondo-like contribution, $\rho_{\text{imp}}(T)$, is observed for $T < 10K$. The origin of this anomaly is not due to magnetic impurities, since the susceptibility is diamagnetic.

In this Letter, we show that the unusual concentration and low temperature dependence of a number of normal state properties of Pb$_{1-x}$Tl$_x$Te can be naturally explained within a picture of dilute Tl impurities acting as negative $U$ centers in the PbTe host. Such a dilute impurity description is suggested by the observed concentration dependence of many properties, as summarized above, e.g., the linear dependence on $x$ of the residual resistivity for $x > x_c$. We model the Tl impurities by the negative $U$ Anderson model and solve this for the static and dynamic properties by using the numerical renormalization group (NRG) method. Our results, with comparisons to experimental data, and previous experimental and theoretical work on Pb$_{1-x}$Tl$_x$Te, provide strong evidence that the CK effect is realized in this system.

The idea that doping PbTe with Tl induces resonant states in the valence band of PbTe was conjectured early on (see Ref. [1]). These states are mainly of Tl $s$-character and lie close to the top of the valence band, as recently shown by density functional theory calculations. Resonant states alone, however, and generalizations of this to an impurity band of resonant states, cannot explain properties such as the superconductivity of Pb$_{1-x}$Tl$_x$Te. For this, a coupling of Tl ions to the lattice, or a static mixed valence model, has been proposed. In the latter, Tl impurities, known to be valence skippers in compounds, are assumed to dissociate into energetically close Tl$^1$ (6$s^2$p$^1$) and Tl$^{1+}$ (6$s^0$p$^3$) ions, while the Tl$^{2+}$ (6$s^0$p$^2$) configuration lies higher in energy.
Thus, charge neutrality implies $n_{\text{p}}$ from the valence band leaving behind
where the number of accepted electrons in the $6^{\text{th}}$ band of PbTe, where
is the matrix element for the
creates an electron with energy $\epsilon_k$. The second term, $H_{\text{imp}} = (\epsilon_0 - \mu_e) \sum_{i=1}^n \tilde{n}_{i\sigma} + U \sum_{i=1}^n n_{1\upsilon} n_{i\sigma}$, describes the Tl impurities, where $n_{i\sigma} = s_{i\sigma}$ is the number operator for a Tl $s$-electron at site $i$ with spin $\sigma$ and energy $\epsilon_0$, and $U$ is the (negative) correlation energy.

The last term, $H_{\text{hyb}} = \sum_{i=1}^n \sum_{\kappa} V_0 (c_{\kappa \sigma} s_{\kappa \sigma} + \text{h.c.})$, models the hybridization of Tl $s$-states with the valence band $p$-states and $V_0$ is the matrix element for the $s$-p interaction. Its strength is characterized by the hybridization function $\Delta(\omega) = \pi V_0^2 \sum_{\kappa} \delta(\omega - \epsilon_{\kappa})$ = $\pi V_0^2 N(\omega)$, where we retain the full energy dependence of the $p$-band density of states $N(\omega)$ = $\sum_{\kappa} \delta(\omega - \epsilon_{\kappa})$ of PbTe [22].

The chemical potential $\mu_e$ determines $n_e = \frac{1}{2} \sum_{\kappa} \langle c_{\kappa \sigma}^\dagger c_{\kappa \sigma} \rangle$ and $n_s = \frac{1}{2} \sum_{\kappa} \sum_{i=1}^n \sum_{\sigma} \langle n_{i\sigma} \rangle$, the average number of $p$ and $s$ electrons per site. We denote by $x = n/N$ the concentration of Tl impurities. Since Tl acts as an acceptor, the ground state corresponds to the $Tl^{1+}$ ($n_s = 2$) configuration and the $Tl^{3+}$ ($n_s = 0$) configuration is split-off from the ground state by the energy $\delta = E(Tl^{3+}) - E(Tl^{1+}) > 0$. A concentration $x$ of Tl impurities accommodates $x(n_s - 1)$ electrons (per Tl site), where the number of accepted electrons in the 6s level of Tl is measured relative to the neutral Tl$^{2+}$ ($s^1$) configuration having $n_s = 1$. These electrons are removed from the valence band leaving behind $n_0 = 1 - n_e$ holes. Thus, charge neutrality implies $n_0 = x(n_s - 1)$ [2], which for a given $x$ and temperature $T$ has to be satisfied by adjusting the chemical potential $\mu_e$. Here, we neglect interimpurity interactions and solve $H$ for a collection of single independent negative-$U$ centers by using the NRG [13]. For each $x$ and each $T$ we satisfy the above equation by self-consistently determining the chemical potential $\mu_e$ (or equivalently the hole chemical potential $\mu_e$, which we henceforth use).

The electrical resistivity of electrons scattering from a dilute concentration $x$ of Tl impurities is obtained from the usual expression, $\rho_{\text{imp}}(T) = 1/e^2 L_{11}$, where $L_{11}$ is the static limit of the current-current correlation function. In the absence of nonresonant scattering the vertex corrections vanish and the relevant transport integral $L_{11}$ can be written as [22],

$$L_{11} = \sigma_0 \int_{-\infty}^{\infty} d\omega \left( -\frac{\partial f(\omega)}{\partial \omega} \right) N(\omega) \tau(\omega, T),$$

where $\sigma_0 = (v_F^2)$ is the velocity factor $v_F^2$ averaged over the Fermi surface, $f(\omega) = 1/[1 + \exp(\omega/k_BT)]$ is the Fermi function, $\tau(\omega, T)$ is the conduction-electron transport time $\tau(\omega, T)^{-1} = 2n_{\text{Tl}} V_0^2 A(\omega, T)$ and $A(\omega, T) = -\frac{1}{2} \text{Im} G(\omega + i0^+)$ is the spectral function of $s$-electrons.

The number of Tl impurities $n_{\text{Tl}}$ per cm$^3$ is related to $x$ in percent by $n_{\text{Tl}} = 1.48 \times 10^{20} x$ [24].

Choice of model parameters.— We use $\mu^* \approx 225$ meV, close to the value obtained from tunneling experiments [12, 13]. Other parameters, such as $\Delta_0 = \Delta(\mu^*)$, required to fix the hybridization function $\Delta(\omega)$, and $U$ are largely unknown. Our interpretation of the tunneling spectra (see discussion of Fig. 2 below), suggests $U \approx -30$ meV. The measured Kondo-like resistivity for $x \geq x_c$ at low temperatures requires that $|U| \gg \Delta_0$. We take $U/\Delta_0 = -11$ with $\Delta_0 = 2.7$ meV to yield a Kondo temperature $T_K \approx 1.23$ K below the highest $T_c \approx 1.5$ K at $x = 1.5 \% \gg x_c$, where $T_K$ is defined via the impurity resistivity $\rho_{\text{imp}}(T) = T_K = 0.5 \rho_{\text{imp}}(T = 0)$ for $x \gg x_c$. The overall qualitative aspects of our results remained the same for values of $U$ in the range 10 meV $\leq |U| \leq 220$ meV and $|U|/\Delta_0 \gg 1$.

Qualitative considerations.— It is instructive to first make some qualitative remarks, starting from the atomic limit $V_0 = 0$ [7]. For $x = 0$ the chemical potential lies in the gap between the valence and conduction bands. For finite but very small $x$ each Tl impurity accepts one electron, i.e. $n_s \approx 2$ and $n_0 = (n_s - 1) \approx x$ grows linearly with $x$. At the same time, the chemical potential shifts downwards into the valence band $\mu < E_v$, where $E_v$ denotes the top of the valence band. This implies that the splitting $\delta(\mu) = -(2(\epsilon_0 - \mu + U))$ between donor and acceptor configurations decreases. Eventually, at a critical concentration $x = x_c$, the chemical potential reaches $\mu = \mu^* = \epsilon_0 + U/2$ where $\delta(\mu) = 2(\mu - \mu^*) = 0$ and the system is in a (static) mixed valence state where the $Tl^{1+}$ and $Tl^{3+}$ configurations are degenerate. In this situation $n_s = 1$, and further doping cannot increase the hole carrier density beyond the value $n_0(\mu^*)$, i.e. one has
self-compensation with a pinning of the chemical potential to $\mu^*$.

For finite $V_0$, quantum fluctuations between the degenerate states $\text{TI}^{1+}$ and $\text{TI}^{3+}$ at $\mu = \mu^*$ become important and lead to a CK effect. This significantly affects all static and dynamic properties and needs to be taken into account in describing the experiments. It is also important for $\mu > \mu^*$, since a finite charge splitting $\delta(\mu) > 0$ in the negative-$U$ Anderson model is similar to a Zeeman splitting in the conventional spin Kondo effect. The latter is known to drastically influence all properties. Thus, for the whole range of concentrations $x$, one expects fluctuations to play an important role in the properties of $\text{Pb}_{1-x}\text{TI}_x\text{Te}$.

**Numerical results.**—Figure 1 shows $n_0(x)$ versus $x$ at $T = 1.8\,\text{K}$ and at $T = 77\,\text{K}$ and a comparison with experimental data on Hall number measurements. At low dopings, $n_0$ is linear in $x$ both in theory and in experiment, as expected for TI impurities acting as acceptors (dot-dashed curve in Fig. 1). However, the efficiency, $n_0(x)/n_{\text{TI}}(x)$, of TI dopants in supplying holes at low $x$ is only around 65% in the data of Ref. 12 as opposed to 100% in our model calculations and in the data of Ref. 8. At higher dopings $n_0(x)$ saturates rapidly with increasing $x$ for $T = 1.8\,\text{K}$ and more slowly at higher temperatures. The theoretical crossover from linear to saturated behavior occurs at $x = x^* \approx 0.5\%$, larger than the value $x_c \approx 0.3\%$ for the onset of superconductivity. The theoretical saturation density $n_0 \approx 0.7 \times 10^{20}/\text{cm}^3$ is close to the experimental value 12. The self-compensation effect for $x \gg x^* \approx 0.5\%$ is a characteristic signature of the CK state: on entering this state the TI ions fluctuate between $\text{TI}^{1+}$ and $\text{TI}^{3+}$ so the average valence is $\text{TI}^{2+}$, which corresponds to no additional electrons being accepted or donated. The CK state may be destroyed by lifting the degeneracy of the pseudospin states, i.e. in the language of the spin Kondo effect, by applying a "magnetic field". A "magnetic field" in the CK effect corresponds to doping or shifting $\mu$. This has been achieved by counterdoping with In ions, which act as donors. The Kondo anomalies, e.g. in the resistivity, were observed to vanish, providing further support to the CK picture. The self-compensation effect can be seen also in the pinning of the hole chemical potential $\mu$ for $x > x^*$, shown in Fig. 1. For $x < x^*$, $\mu$ grows nonlinearly with $x$ and rapidly approaches the value $\mu^* = 225\,\text{meV}$ for $x > x^*$, both at $T = 1.8\,\text{K}$ and at $T = 77\,\text{K}$.

Figure 2 shows the TI s-electron spectral function $A(E, T = 0)$ at zero temperature and different dopings $x$. For small doping, $x < x^*$, the hole chemical potential $\mu$ lies above $\mu^*$ within the shallow part of the valence band density of states $N(E)$ (see Fig. 2(a)), consequently the splitting $\delta(\mu) = 2(\mu - \mu^*)$, see Fig. 1, is large. Such a large splitting acts like a large Zeeman splitting in the conventional positive $U$ Anderson model and polarizes the spectral function so that its weight lies mostly below the Fermi level $E_F$. For $x \geq x^*$, $\mu$ approaches $\mu^*$ and a CK effect develops. The spectral function develops a sharp asymmetric Kondo resonance close to, but below $E_F$, and an upper Hubbard satellite peak appears above $E_F$. Early tunneling experiments for low dopings $x < 0.3\%$ showed only one resonant level below $E_F$, whereas more recent tunneling experiments for $x > 0.6\%$ show two "quasilocal" peaks, a narrow one of width 6 meV close to $E_F$ and a broader one of width 12 meV at a nearly constant energy 13-15 meV.
below this. Interpreting these as the Kondo resonance and the lower Hubbard satellite peaks in Fig. 2 yields \(|U|/2 \approx 15 \text{ meV}\) and hence the value \(U \approx 30 \text{ meV}\) used in our calculations. Since the CK resonance is temperature dependent \(\rho_{\sigma}\), the above interpretation could be tested with temperature dependent studies of tunneling or high resolution photoemission spectra.

The temperature and doping dependence of the impurity resistivity, \(\rho_{\text{imp}}\), is shown in Fig. 3. For \(x < x^*\), Tl impurities act as acceptors with a well-defined valence state \((\text{TI}^{1+})\). They therefore act as weak potential scatterers and consequently the resistivity is much below the unitary value, as seen in Fig. 3. For \(x > x^*\), dynamic fluctuations between the nearly degenerate \(\text{TI}^{1+}\) and \(\text{TI}^{3+}\) states leads to the CK effect and \(\rho_{\text{imp}}\) approaches the resistivity for unitary scatterers at \(T = 0\). For \(x > x^*\), \(\rho_{\text{imp}}\) is well described by the spin Kondo resistivity \(\rho_{\sigma}\) (open squares, Fig. 3) with a logarithmic form around \(T \approx T^*_K\), where \(T^*_K\) is an effective Kondo scale, and \(T^2\) Fermi liquid corrections at low \(T \ll T^*_K\), in qualitative agreement with experiment 4. The effective Kondo scale \(T^*_K\) is a function of the charge splitting \(\delta (\mu)\) and \(T_K\), and approaches the true Kondo scale \(T_K\) only asymptotically for \(x \gg x^*\) (see legend to Fig. 3). Finally, Fig. 3a shows that the impurity residual resistivity is significant only when the CK effect is operative, i.e. for \(x > x^*\), in qualitative agreement with experiment 4, 5.

Conclusions.— In summary, we investigated the normal state properties of \(\text{Pb}_{1-x}\text{TI}_x\text{Te}\) within a model of Tl impurities acting as negative \(U\) centers. Our NRG calculations support the suggestion that the CK effect is realized in \(\text{Pb}_{1-x}\text{TI}_x\text{Te}\) \(\rho_{\sigma}\). They explain a number of low temperature anomalies of \(\text{Pb}_{1-x}\text{TI}_x\text{Te}\), including the qualitatively different behavior below and above the critical concentration \(x^*\), where \(x^* \approx 0.5\%\) is close to \(x_c \approx 0.3\%\) for the onset of superconductivity. At \(x = x^*\), two nonmagnetic valence states of \(\text{TI}\) become almost degenerate and the ensuing pseudospin CK effect results in a Kondo anomaly in the resistivity for \(x > x^*\) and a residual resistivity approximately linear in \(x\). Our results for these quantities and the carrier density \(n_d(x)\) are in good qualitative agreement with experiments 5, 6, 7, 8, 9, 10, 11.

For the Tl s-electron spectral function, we predict that one peak should be present far below \(E_F\) for \(x < x^*\) and that a second temperature dependent Kondo resonance peak develops close to, but below \(E_F\), on increasing \(x\) above \(x^*\). This provides a new interpretation of measured tunneling spectra 10, which could be tested by temperature dependent studies of tunneling or photoemission spectra. In the future, it would be interesting to extend this work to include the effects of disorder within an Anderson-Hubbard model description.
