ABSTRACT
We give the first polynomial-time algorithm to estimate the mean of a $d$-variate probability distribution with bounded covariance from $\tilde{O}(d)$ independent samples subject to pure differential privacy. Prior algorithms for this problem either incur exponential running time, require $\Omega(d^{1.5})$ samples, or satisfy only the weaker concentrated or approximate differential privacy conditions. In particular, all prior polynomial-time algorithms require $d^{1+\Omega(1)}$ samples to guarantee small privacy loss with "cryptographically" high probability, $1 - 2^{-d^{\Omega(1)}}$, while our algorithm retains $\tilde{O}(d)$ sample complexity even in this stringent setting.

Our main technique is a new approach to use the powerful Sum of Squares method (SoS) to design differentially private algorithms. SoS proofs to algorithms is a key theme in numerous recent works in high-dimensional algorithmic statistics – estimators which apparently require exponential running time but whose analysis can be captured by low-degree Sum of Squares proofs can be automatically turned into polynomial-time algorithms with the same provable guarantees. We demonstrate a similar proofs to private algorithms phenomenon: instances of the workhorse exponential mechanism which apparently require exponential running time but which can be analyzed with low-degree SoS proofs can be automatically turned into polynomial-time differentially private algorithms. We prove a meta-theorem capturing this phenomenon, which we expect to be of broad use in private algorithm design.

Our techniques also draw new connections between differentially private and robust statistics in high dimensions. In particular, viewed through our proofs-to-private-algorithms lens, several well-studied SoS proofs from recent works in algorithmic robust statistics directly yield key components of our differentially private mean estimation algorithm.

1 INTRODUCTION
Mean estimation is perhaps the most elementary statistical task: given samples from a probability distribution $D$, estimate its expected value. In this paper, we study mean estimation in $d$ dimensions subject to differential privacy (DP) [27], a rigorous notion of data privacy. Privacy is of natural concern in high-dimensional statistics, where data may be sensitive and standard estimators like the empirical mean may leak information about individuals in a dataset (see, e.g., privacy attacks in [15, 24, 29, 32] and the survey [28]). On the other hand, privacy and statistical estimation seem largely compatible: in the large-sample limit, good statistical estimators will have vanishing dependence on each individual sample anyway. Indeed, even though the empirical mean (the natural benchmark for accuracy in mean estimation) is not differentially private, estimators are known which match its accuracy guarantees while also providing differential privacy [13, 43]. Namely, an accurate and private estimate of the mean can be obtained using $n = O(d)$ samples. However, known estimators achieving this sample complexity require exponential running time.

If one instead focuses on polynomial-time algorithms, existing estimators all face significant drawbacks: either they require $n \geq d^{1+\Omega(1)}$ samples, or they may leak private information with probability $2^{-d^c}$ for small $c > 0$ [31, 39, 43]. (In privacy language, they satisfy only concentrated or approximate differential privacy.) Since a major goal of privacy is to make strong assurances on leakage of sensitive information, best practices disallow private data leakage even with “cryptographically” small probability $2^{-\text{poly}(d)}$. One way to satisfy this stringent requirement is to provide pure differential privacy, which disallows substantial leakage of private information with any nonzero probability. Thus, the main question in our paper is:

Is there a polynomial-time pure DP algorithm for mean estimation using $n = O(d)$ samples?
Our main result answers this question affirmatively, up to logarithmic factors. To state our main result, we define differential privacy:

Definition 1 ((Pure) Differential Privacy). For $\varepsilon > 0$, a (randomized) algorithm $A$ which takes $n$ inputs $X_1, \ldots, X_n$ is $\varepsilon$-differentially private ($\varepsilon$-DP) if for every pair of inputs $X_1, \ldots, X_n$ and $X'_1, \ldots, X'_n$ such that $X_i = X'_i$ for all except a single index $i \in [n]$ and for all possible events $S \subseteq \text{Range}(A)$,

$$
P(A(X_1, \ldots, X_n) \in S) \leq e^\varepsilon \cdot P(A(X'_1, \ldots, X'_n) \in S).
$$

Theorem 2 (Main Theorem). For every $n, d \in \mathbb{N}$ and $R, \alpha, \varepsilon, \beta > 0$ there is a polynomial-time $\varepsilon$-DP algorithm such that for every distribution $D$ on $\mathbb{R}^d$ such that $\|\mathbb{E}_{X \sim D} X\| \leq R$ and $\text{Cov}_{X \sim D}(X) \preceq I$, given $X_1, \ldots, X_n \sim D$, with probability $1 - \beta$ the algorithm outputs $\hat{\mu}$ such that $\|\hat{\mu} - \mathbb{E}_{X \sim D} X\| \leq \alpha$, so long as

$$
n \geq \hat{O}(d \log(1/\beta) + d \log R + \min(d, R) \cdot \log(1/\beta)) + \frac{d \log R \cdot \min(d, R)}{\varepsilon}.
$$

Furthermore, if an $n$-fraction of the samples $X_1, \ldots, X_n$ are adversarially corrupted, the algorithm maintains the same guarantee, at the cost that now $\|\hat{\mu} - \mathbb{E}X\| \leq \alpha + O(\sqrt{n})$.

The sample complexity of our algorithm is nearly linear in $d$, thereby answering our main question up to logarithmic factors. Beyond this core goal, we highlight that our algorithm is also robust to adversarial contaminations and enjoys sub-Gaussian confidence intervals when $n \gg d \log R \cdot \min(d, R) \cdot \log(1/\beta)$, both sought-after features in recent non-private algorithms [17, 21, 33, 49]. The sample complexity of our algorithm is nearly optimal, with the exception of the term $(\log(1/\beta) \cdot \min(d, R)) / \varepsilon$ – see the full version of the paper for the corresponding lower bounds. (Put differently, information-theoretically it is possible to achieve sub-Gaussian confidence intervals under the slightly milder assumption

$$
n \gg d \log R + \min(d, R) \cdot \log(1/\beta).
$$

Beyond clip-and-noise. Obtaining the guarantees of our algorithm requires going beyond existing techniques for private mean estimation, which we briefly review. A common technique in differential privacy is to “just add noise.” More precisely, suppose that $f(X_1, \ldots, X_n)$ is a bounded sensitivity function of $n$ inputs, meaning that replacing a single input $X_i$ with an arbitrary $X'_i$ changes the value of $f$ by at most $\Delta$ (in an appropriate choice of norm). Then, $f(X_1, \ldots, X_n) + Z$ will be private, where $Z$ is an appropriate random variable whose magnitude depends on $\Delta$.

Existing polynomial-time algorithms for private mean estimation all take this approach. First, to limit the sensitivity of the empirical mean, the algorithms clip the samples $X_1, \ldots, X_n \in \mathbb{R}^d$ to lie in an $\ell_2$ ball. Considering the case $\text{Cov}(X) \preceq I$, we will have $\|X - \mathbb{E}X\| \approx \sqrt{d}$, so using a ball of radius at least $\sqrt{d}$ is unavoidable without introducing too much error in the clipping phase. Then, the algorithms output $\hat{\mu} + Z$, where $\hat{\mu}$ is the empirical mean of the clipped samples.

If one takes the coordinates of $Z$ to be draws from a Laplace distribution, the resulting algorithm will satisfy $\varepsilon$-DP, but the relatively heavy tails of the Laplace distribution impose a cost that $n$ must be at least $d^{3/5}/\varepsilon$ to obtain nontrivial guarantees. On the other hand, if $Z$ is Gaussian, the resulting algorithm appears to tolerate $n \approx d/\varepsilon$ samples, but it no longer satisfies pure DP. Instead, to guarantee privacy loss at most $\varepsilon$ with probability at least $\delta$ over the internal randomness in the algorithm, $n \geq d \sqrt{\log(1/\delta)/\varepsilon}$ is required (i.e. the algorithm satisfies concentrated DP), meaning that for “cryptographically small” $\delta$, this algorithm, too, has super-linear sample complexity.

One might naturally suspect, therefore, that strong privacy guarantees like this simply require $\Omega(d^{1.5})$ samples. Indeed, if nastier distributions than we consider here (violating bounded covariance) are allowed, these two bounds of $\Omega(d^{1.5})$ and $\Omega(d)$ are known to be tight for pure and concentrated DP, respectively [15, 31, 39], and similar separations were previously conjectured even for bounded-covariance distributions [13].

However, [43] (building on related techniques of [13]) show that in exponential time one can go beyond the clip-and-noise approach to mean estimation. In particular, a tournament-based approach gives a pure-DP algorithm using $O(d/\varepsilon)$ samples. We obtain nearly-matching guarantees in polynomial time – ours is the first polynomial-time private algorithm to go beyond the clip-and-noise approach.

Sum-of-Squares Proofs to Private Algorithms. Proofs to Algorithms has become a powerful algorithm-design technique in computational high-dimensional statistics. Roughly speaking, the proofs to algorithms technique shows that statistical estimation problems which can be solved to a given accuracy by some (not necessarily polynomial-time) estimator can actually be solved in polynomial time with the same accuracy if the analysis of that estimator can be captured by a certain restricted but powerful formal proof system, known as the SoS proof system. This insight has had major consequences in robust and heavy-tailed statistics, clustering, learning latent variable models, and beyond. (For instance, [35, 47, 48, 59], and the survey [61].)

We show that this approach also applies to private algorithm design. Our techniques give a generic method to turn (potentially) exponential-time instances of the workhorse exponential mechanism, whose breadth of applicability is hard to overstate [58], into polynomial time algorithms, when their analyses are captured by the same SoS proof system. This gives us the following proofs-to-algorithms principle for private algorithm design, which we anticipate will be widely applicable:

Proofs to Private Algorithms (see Theorem 11): Instances of the exponential mechanism with low-degree SoS proofs of bounded sensitivity and utility automatically yield computationally-efficient private algorithms.

(See Section 2 for a description of the exponential mechanism and more on SoS proofs.) We are able to capture this principle as a formal meta-theorem, Theorem 11 – since its statement requires a few more technical definitions than we are ready to state, we defer it for now.

Convex Programming and Private Algorithms. Like nearly all applications of the Sum of Squares method, algorithms which result from our proofs-to-private-algorithms approach ultimately use convex programs – semidefinite programs, in our case. Our techniques
give a substantially novel approach to convex programming in private algorithms. Prior works largely do this in one of two ways. Some privatize the input before applying a convex program to it (e.g., privatizing a graph and then post-processing with convex programming [11, 30]). This can be limiting, as the convex program cannot itself be helpful in achieving privacy, only in some post-processing. Other algorithms use a private solver for the convex program itself [37, 52]. This can be quite technically challenging: few DP solvers for convex programs are known, and in particular, we are not aware of any generic DP algorithm for solving semidefinite programs.

Instead, our algorithms hide convex programs behind the exponential mechanism. Namely, we use convex programs as score functions. (Again, see Section 2 for an explanation of this terminology.) Our key insight is: when convex programs are married to the exponential mechanism in the correct way, the resulting exponential mechanisms can be implemented in polynomial time using private log-concave sampling algorithms. This builds directly on [9], who use a similar approach but for much simpler un-constrained convex optimization problems resulting from empirical risk minimization problems. The analysis of this interplay of exponential mechanism and convex programming is completely generic – meaning it has nothing to do with the particular setting of mean estimation – and is captured in the proof of our (meta)-Theorem 11.

Robust Statistics and Privacy. Robust statistics, the study of statistics in the presence of corrupted samples, has enjoyed a recent renaissance [22]. Robustness and privacy are at least spiritual cousins – both demand that a statistical estimator not change its behavior “too much” when one or several samples are replaced arbitrarily. However, the formal requirements for robustness and privacy are rather different. The output of a good robust mean estimator should not move far in Euclidean distance when 1% of the samples it is given are corrupted by a malicious adversary. Privacy, by contrast, demands that the distribution of outputs of an algorithm not shift too much when any single sample is replaced by another.

In spite of this formal difference, [26] was able to use robust estimators in one dimension to construct private estimators. This suggests that the flurry of recent algorithms for high-dimensional robust statistics with strong provable guarantees should yield high-dimensional private estimators.

Our work makes good on this promise. In particular, our algorithm for private mean estimation ultimately employs a well-studied Sum-of-Squares SDP from robust mean estimation, and our analysis applies several SoS proofs originally formulated to analyze that SDP in robust statistics. Thus, our proofs-to-private-algorithms approach gives a lens through which algorithms from robust statistics can yield private algorithms.

Lastly, there is an even more direct connection between our particular result and recent developments in robust statistics. The robustness renaissance was kicked off by [20, 49], which gave the first polynomial-time algorithms for robustly learning a Gaussian where corrupted samples can be tolerated with dimension-independent error. Prior polynomial-time algorithms for the same problem have guarantees no better than what can be obtained by naive sample-clipping, and as a result incur error scaling as $\eta \cdot \text{poly}(d)$ when an $\eta$-fraction of samples are corrupted. Just as [20, 49] gave the first algorithms with guarantees going beyond naive sample clipping in the robust setting, our work is the first to go beyond clip-and-noise in the private setting.

Related Work. A mature body of work focuses on private mean estimation. The most relevant results restrict the underlying distribution to satisfy a moment bound (including sub-Gaussianity), examples include [1, 4, 8, 10, 12, 14, 16, 25, 38–41, 43, 46, 65]. All prior study of the multivariate case either focuses on concentrated or approximate DP, or provides computationally-inefficient algorithms for pure DP. We are the first to give an efficient $O(d)$-sample algorithm for multivariate mean estimation under pure DP. This matches the sample complexity of the best known algorithms under concentrated DP, while simultaneously strengthening the privacy guarantee.

Other prior work studies private mean estimation of arbitrary (bounded) distributions [15, 29, 63]. Interestingly, in this case, the optimal sample complexity under pure and concentrated DP are separated by a factor of $\sqrt{d}$, leading to the naive Laplace mechanism being effectively optimal. It appears that our bounded moments assumption induces a qualitatively different structure, which eliminates the benefits of relaxing to concentrated DP. Pinpointing the precise conditions under which a separation occurs remains an interesting direction for future work.

Other works study private statistical estimation in different and more general settings, including mixtures of Gaussians [2, 42], graphical models [67], discrete distributions [19], and median estimation [5, 64]. Some recent directions involve guaranteeing user-level privacy [51, 54], or a combination of local and central DP for different users [6]. See [44] for further coverage of DP statistical estimation.

Several other works employ sampling-based methods to efficiently implement the exponential mechanism [3, 9, 45, 50], [3, 45, 50] construct sophisticated sampling algorithms by hand to sample from a non-log-concave distributions; by contrast, we use convex programming to construct our score functions, ensuring that we always stay within the realm of log-concave sampling algorithms. [9] constructs the private log-concave sampler we use in our work, but they employ it only to sample from comparatively simple log-concave distributions arising from empirical risk minimization of convex loss functions. A recent work of [57] provides a faster algorithm for private log-concave sampling.

Another recent line of work studies sub-Gaussian confidence intervals for mean estimation of heavy-tailed distributions (i.e., assuming only bounded covariance). Lugosi and Mendelson [56] proposed an inefficient algorithm, with an SoS-based algorithm coming in [33]; see also the survey [55]. Some works considered efficient algorithms for simultaneously robust and heavy-tailed mean estimation [18, 23, 60]. A recent result shows that the core solution concepts for robust and heavy-tailed mean estimation can be considered equivalent [36]. Our work demonstrates that the line of efficient estimators inspired by [33] is simultaneously effective for robust, heavy-tailed, and private mean estimation.

Relatively limited work simultaneously considers privacy and the other constraints of robustness and heavy-tailed estimation. The main result is [52] which considers robust and private mean estimation. Our result can be seen as improving on the running
Table 1: Comparing private mean estimation algorithms for distributions with bounded covariance. (Some papers contain several algorithms.) Sample complexity column ignores logarithmic factors in $d$. "-" indicates that we are not aware of any analysis in the literature.

| Algorithm | Sample Complexity | Privacy | Sub-Gaussian Rates | Robust | Poly Time |
|-----------|-------------------|---------|--------------------|--------|----------|
| Sample Mean | $d$ | None | No | No | Yes |
| [43]-A | $d$ | Pure | - | Yes | No |
| [43]-B | $d$ | Concentrated | No | No | Yes |
| [43]-C | $d^{1.5}$ | Pure | No | No | Yes |
| [52]-A | $d$ | Approximate | - | Yes | No |
| [52]-B | $d^{1.5}$ | Concentrated | No | Yes | Yes |
| Theorem 2 | $d$ | Pure | $n \gg \frac{d \log R \min(d, \log R) (\log(1/\beta))}{\varepsilon^2}$ | Yes | Yes |

time or sample complexity of their two algorithms, and the privacy guarantee of both. While other prior works focus on heavy-tailed distributions [8, 40, 43, 65], these do not address the primary goal in the non-private setting, which is to achieve sub-Gaussian rates with respect to the error probability. Instead, they generally prove guarantees with constant probability of success, which can be boosted at the cost of a multiplicative (rather than additive) logarithmic factor which is inverse in the failure probability. Note that some of the previous (inefficient) cover- and median-based approaches to private estimation [1, 12, 13, 43, 52] have varying levels of robustness and sub-Gaussian rates for heavy-tailed settings. However, none of their results give computationally efficient estimators for pure DP. A simultaneous and independent work of [53] demonstrates an interesting connection between resilience [62] and private estimation. They exploit this connection to design robust and private algorithms for a variety of settings, including mean estimation, covariance estimation, PCA, and more. However, their focus is on providing inefficient algorithms under the constraint of approximate DP, while our goal is to give a framework for efficient algorithms under pure DP. For a summarized comparison of our work with recent private algorithms, see Table 1.

2 TECHNIQUES

2.1 The SoS Exponential Mechanism

Before we turn to our algorithm for mean estimation, we offer a little more detail on the proofs-to-private-algorithms approach and its core component, which we call the SoS exponential mechanism. We begin with a review of the exponential mechanism itself.

The Exponential Mechanism. Consider the general problem of privately selecting one among a set of candidates $C$ given a dataset $X$, where the quality of a candidate $x \in C$ depends on the dataset $X$. The candidates $C$ could represent many different things depending on the context. In a statistical setting one may often think of $C$ as a class of probability distributions, $X$ as a list of samples from one of those distributions, and the goal is to select the distribution from which $X$ came (up to small error).

To apply the exponential mechanism for this problem, one first finds a score function $s(X, x)$ which assigns a (real-valued) score to each dataset-candidate pair, ideally such that $x$’s which are "good" for a given $X$ receive high scores. Given $X$ and a privacy parameter $\varepsilon > 0$, the exponential mechanism will sample a random $x$ with probabilities $\mathbb{P}(x) \propto \exp(\varepsilon \cdot s(X, x))$. The output is $\varepsilon$-differentially private so long as the score function satisfies a bounded sensitivity property: for any pair of neighboring datasets $X, X'$ and for all $x \in C$, one has $|s(X, x) - s(X', x)| \leq 1$.

Beyond privacy, one also wants the resulting $x$ to be useful. While this can also mean different things depending on the context, we will take “utility” to mean that $x$ is close to some good $x^*(X)$.

To prove that this happens for the exponential mechanism defined above, one shows:

1. High-scoring $x$’s are good: if $s(X, x) \geq 0$, then $\|x - x^*\| \leq \alpha$, for a small $\alpha > 0$. (The choice of 0 is without loss of generality; the mechanism is invariant under additive shifts of $s$.)

2. Not too few high-scoring $x$’s: $\frac{|\{x \in C : s(X, x) \geq \varepsilon\}|}{|C|} \geq \frac{1}{\varepsilon}$. (If $C$ is an infinite set one can replace $|\cdot|$ with some measure of volume.)

Then a simple argument shows that $x$ such that $\|x - x^*\| \leq \alpha$ is selected with probability at least $1 - \exp(-\varepsilon \alpha)$. In other words, the mechanism selects a good $x$ so long as $t \gg \frac{\log \varepsilon}{\varepsilon^2}$.

The exponential mechanism can lead to computationally inefficient algorithms for two basic reasons. First, in high-dimensional statistics it is often natural to use score functions which seem hard to compute – the Tukey depth, for just one example [12, 52]. Second, as we will face when we turn to mean estimation, even with score functions that are easy to compute, sampling $x$ with $\mathbb{P}(x) \propto \exp(\varepsilon \cdot s(X, x))$ may not be computationally tractable.

Convex programs as score functions The SoS exponential mechanism can address both of these sources of intractability for instances of the exponential mechanism where the proofs of bounded sensitivity are captured in a powerful formal proof system, the Sum of Squares proof system (SoS). To de-mystify this a little without yet delving into the details of SoS proofs, we can see a high-level picture of the algorithms which use the SoS exponential mechanism. Ultimately, these algorithms fit into the exponential mechanism framework, but with special score functions.

To wit, suppose that we can arrange for the score function $s(X, x)$ to take the form of a linear optimization problem over a convex set of bounded sensitivity and sub-Gaussian rates for heavy-tailed distributions.

\footnote{We say $X, X'$ are neighboring if they differ on the presence/absence of just one individual.}
\(\mathcal{K}(X)\) with an additional linear constraint involving \(x\):

\[
s(X, x) = \max_{y \in \mathcal{K}(X)} (c, y) \text{ such that } Ay = x
\]

for some matrix \(A\) and vector \(c\). As long as \(\mathcal{K}(X)\) admits a computationally efficient separation oracle, \(s(X, x)\) will be polynomial-time computable – this already addresses the first source of potential intractability in the exponential mechanism. A simple argument shows even more: for each \(X\), \(s(X, x)\) is actually concave in \(x\). Thus, the distribution \(P(x) \propto \exp(-s(X, x))\) is log-concave, so we can (usually) sample from it in polynomial time! This sampling step itself has to be done privately: luckily for us, log-concave sampling is so well understood that private methods for polynomial-time log-concave sampling are known [9].

The restriction that the score function take the form of an optimization problem is not a major one: many useful score functions in high-dimensional statistics, such as the Tukey depth, are naturally expressible in this way. But how to find a score function which is simultaneously a convex optimization problem and maintains both bounded sensitivity and utility? The SoS method gives us a way to construct such a score function automatically, starting from any score function which is expressible as a (potentially non-convex) optimization problem, and for which the proofs of bounded sensitivity and utility are expressible in the SoS proof system.

### 2.2 Private Mean Estimation

We proceed with a high-level description of our algorithm for private mean estimation and its analysis. One could obtain our algorithm as an instance of proofs-to-private-algorithms, by:

- Constructing a certain simple-to-analyze exponential mechanism-based mean estimator.
- Writing the simple analysis as a series of SoS proofs and applying (meta)-Theorem 11.

However, so that our algorithm can be understood without tackling the SoS exponential mechanism in full generality, we will now give a more concrete description of the algorithm and its analysis. We give a high level version of this description here, and in the main body of our paper we actually provide a full analysis of the algorithm without appealing to Theorem 11.

Let us recall the setup for our problem. There is a random variable \(X\) on \(\mathbb{R}^d\) with \(\text{Cov}(X) \leq I\) and \(\|EX\| \leq R\). The goal is to estimate \(EX\) from i.i.d. copies \(X_1, \ldots, X_n\), subject to \(\varepsilon\)-DP. The promise \(\|EX\| \leq R\) is information-theoretically necessary for pure differential privacy [13, 46].

Our algorithm has strong guarantees in the presence of adversarially corrupted samples, and obtains sub-Gaussian confidence intervals given heavy-tailed samples. In fact, this is a side-effect of the fact that our algorithm uses well-studied SDPs from the robust statistics setting, viewing them through the SoS exponential mechanism lens to obtain privacy. In particular, folklore adaptations of the analyses in [17, 48] directly show that our algorithm is robust, so to avoid a proliferation of notation we give the proof in the non-robust setting, and remark on the relevant robustness properties.

Like prior algorithms for private mean estimation, our algorithm has two phases.

1. Reduce \(R\) to \(\text{poly}(d)\), roughly by finding a large ball containing a large number of samples.

2. Estimate \(EX\) under the assumption \(\|EX\| \leq \text{poly}(d)\).

We start with the second step, which captures much of our conceptual contribution – even under the assumption \(R \leq \sqrt{d}\), prior algorithms could not achieve pure differential privacy. Then we discuss the first step, where prior algorithms require \(\Omega(d(\log R + \log(1/\beta)))\) samples. We give an algorithm with sample complexity \(\log R(d + \log(1/\beta))\), when \(\log R \ll d\), our algorithm improves over prior work. (Information-theoretically, \(d \log R + \log(1/\beta)\) is possible.)

#### 2.2.1 Private mean estimation when \(\|EX\| \leq \text{poly}(d)\).

Let us write \(\mu = EX\). For simplicity, for now we focus on the case that our goal is to find \(\hat{\mu}\) such that \(\|\hat{\mu} - \mu\| \leq O(1)\) using \(O(d)\) samples. We can reduce from the \(\varepsilon\)-error case to this one by placing the samples in buckets containing around \(1/\varepsilon^2\) samples and taking sample means within each bucket.) We will also think of \(\varepsilon\) as a small constant. A merit of our approach is that it allows powerful techniques from robust statistics to be used for private algorithm design: in this case, our algorithm draws heavily on a robust mean estimation algorithm due to [17], using SoS exponential mechanism to privatize its use of convex programming.

**Iterative refinement/gradient descent.** Our algorithm will iteratively refine an initial estimate of the mean (without loss of generality, the origin), producing a series of estimates \(\hat{\mu}_0 = 0, \hat{\mu}_1, \ldots, \hat{\mu}_T\). In each step \(t\), we will privately find a unit vector \(v\) such that \(\langle v, \mu - \hat{\mu}_t \rangle \geq \Omega(1) \cdot \|\mu - \hat{\mu}_t\|\). Then we can replace \(\hat{\mu}_t\) with \(\hat{\mu}_{t+1} = \hat{\mu}_t + r \cdot v\) for some appropriate step size \(r > 0\). By standard reasoning this means that \(O(\log d)\) steps suffice to obtain \(\|\hat{\mu}_T - \mu\| \leq O(1)\).

This gradient-descent approach introduces only logarithmic overheads into our sample complexity and running time, so now we turn to the heart of our algorithm: privately finding \(v\).

**Finding private gradients.** Given samples \(X_1, \ldots, X_n \in \mathbb{R}^d\) and \(\hat{\mu}_t\), we would like to privately select a unit vector \(v\) such that \(\langle v, \mu - \hat{\mu}_t \rangle \geq \Omega(1) \cdot \|\mu - \hat{\mu}_t\|\). We will use the exponential mechanism, for which we need to define a score function. For this, we are inspired by recent work in robust and heavy-tailed statistics, where the following has become a standard fact [56]:

**Fact 3 (Directions with many outliers are good, informally).** Suppose that \(\|\mu - \mu\| \gg 1\). Then, with high probability over \(X_1, \ldots, X_n\), so long as \(n \gg d\), there are at least \(0.9n\) samples \(X_i\) such that \(\langle X_i - \hat{\mu}_t, \frac{\mu - \hat{\mu}_t}{\|\mu - \hat{\mu}_t\|} \rangle \geq \Omega(1) \cdot \|\mu - \hat{\mu}_t\|\). Furthermore, for every unit vector \(v\) such that

\[
\left| \{i : \langle X_i - \hat{\mu}_t, v \rangle \geq \Omega(1) \cdot \|\mu - \hat{\mu}_t\| \} \right| \geq 0.8n,
\]

we have \(\langle v, \mu - \hat{\mu}_t \rangle \geq \Omega(1) \cdot \|\mu - \hat{\mu}_t\|\).

**Fact 3 makes a good choice of score function clear:** we should use

\[
s(X, v) = |\{i : \langle X_i - \hat{\mu}_t, v \rangle \geq \Omega(1) \cdot \|\mu - \hat{\mu}_t\| \}|.
\]

Utility of this score function is captured by Fact 3, and bounded sensitivity is clear by construction. (In fact, it is exactly this bounded sensitivity property which has already made Fact 3 so important in robust and heavy-tailed statistics.) We do not necessarily know the value of \(\|\mu - \hat{\mu}_t\|\), but getting a private estimate of this quantity is not too difficult – we privatize a procedure due to [17].
A straightforward analysis shows that, since the volume of the $d$-dimensional unit ball is roughly $\exp(d)$, exponential mechanism with this score function will $\epsilon$-privately select a good $v$ so long as $n \gg d/\epsilon$, which is exactly the sample complexity we expect for estimating $\mu$ to error $O(1)$.

Finding private gradients in polynomial time. Of course, the key problem is that sampling with $\mathbb{P}(v) \propto \exp(\epsilon \cdot s(X, v))$ may not be possible in polynomial time. Indeed, a seemingly-easier problem, finding the highest-scoring $v$, seems closely related to computing Tukey depth, which is NP-hard.

However, some hope comes again from robust/heavy-tailed statistics, where approximation algorithms (often based on semidefinite programming) for the problem of finding the highest scoring $v$ have become an invaluable tool. Our starting point is the by-now standard construction of such a semidefinite relaxation, which we brieﬂy review. First, we write this optimization problem as a degree-2 polynomial optimization problem in variables $a_1, \ldots, a_d$ and $b_1, \ldots, b_n$, where the latter are constrained so as to be 0/1 indicators of $(X_i - \mu_i, v) \geq r$ for some threshold value $r$:

$$\max \sum_{k=1}^{n} b_k \text{ such that } ||v||^2 \leq 1,$$

$$b_i^2 = b_i,$$

and $b_i(X_i - \mu_i, v) \geq b_i \cdot r$ for all $i$.

The degree-2 SoS relaxation of this optimization problem optimizes over degree-2 polynomial optimization problem in variables $a_1, \ldots, a_d$ and $b_1, \ldots, b_n$ which are normalized and positive: $\hat{E} 1 = 1$ and $\hat{E} p(b, v)^2 \geq 0$ for all linear $p$. Concretely:

$$\max \hat{E} \sum_{i \leq n} b_i \text{ s.t. } \hat{E} ||v||^2 \leq 1,$$

$$\hat{E} b_i^2 = \hat{E} b_i,$$

and $\hat{E} b_i(X_i - \mu_i, v) \geq r \cdot \hat{E} b_i$ for all $i$. (1)

This optimization problem can be solved via semidefinite programming – the resulting (equivalent) SDP optimizes over $(1 + n + d) \times (1 + n + d)$ block matrices:

$$\max \text{Tr} B \text{ such that } \begin{pmatrix} 1 & \hat{b}^T & \hat{v}^T \\ \hat{b} & B & W^T \\ \hat{v} & W & V \end{pmatrix} \geq 0,$$

$$\text{Tr} V \leq 1, B_{ii} = \hat{b}_i,$$

and $(X_i - \mu_i, W_i) \geq r \cdot B_{ii}$.

Here, $V$ is a proxy for the rank-one matrix $vv^T$ and similarly for $B$ and $bb^T$. This SDP is known to be a good approximation to the problem of finding the maximum-score $v$.

We prove the following fact. (As an aside, this is where SoS proofs enter the picture: establishing facts such as the below for SoS SDP relaxations in general requires constructing SoS proofs.)

**FACT 4 (Bounded Sensitivity and Utility for (1), Informal).**

**Bounded Sensitivity:** Changing a single sample in optimization problem (1) can change the objective value by at most 1. **Utility:** With high probability over $X_1, \ldots, X_n$, if $||\mu - \mu|| \gg 1$, then any feasible $\hat{E}$ in (1) with objective value at least $0.8n$ satisfies $\hat{E}v, \mu - \hat{\mu} \geq \Omega(1) \cdot ||\mu - \mu||$.

While this proves largely adapts similar arguments in the robust statistics literature, there is a key technical innovation. Prior algorithms employing the SDP described above use a nontrivial rounding step to extract a good vector $v$ from the $d \times d$ PSD matrix $V$. However, for reasons we discuss below, to use the SoS exponential mechanism, it is important that $v$ can be read directly off of the SDP (more precisely, that the rounding algorithm used is linear). This means we need a stronger rounding procedure than that used in prior works – we are able to show that $\hat{v} = \hat{E}v$, a simple linear function of $E$, is a good choice.

Sampling with convex programs The “utility” part Fact 4 solves the problem of finding a high-scoring $v$ in polynomial time, via semidefinite programming. But we want to find such a high-scoring $v$ privately.

The key idea is to use the SDP to construct a score function: convexity of the set of feasible solutions and linearity of the objective function now imply log-concavity of the resulting sampling problem! This observation, while simple, is remarkably powerful: it allows us to employ a well-studied SDP from robust statistics nearly out-of-the-box to obtain strong privacy guarantees.

Ultimately, we employ the score function:

$$s(X, v_0) = \max \hat{E} \sum_{i \leq n} b_i \text{ s.t. } \hat{E} ||v||^2 \leq 1,$$

$$\hat{E} b_i^2 = \hat{E} b_i,$$

and $\hat{E} b_i(X_i - \mu_i, v) \geq r \cdot \hat{E} b_i$ for all $i$ and $\hat{E} v = v_0$, together with the private sampling algorithm of [9], to sample from $\mathbb{P}(v_0) \propto \exp(\epsilon \cdot s(X, v_0))$.

We make a few remarks on the precise way that $s(X, v_0)$ depends on $v_0$ that is, via the constraint $\hat{E}v = v_0$, since this choice is not accidental. First of all, it is important that the constraints of the optimization problem defining $s(X, v_0)$ depend linearly on $v_0$; otherwise we might not retain log-concavity of the resulting sampling problem. We can do this only because the rounding algorithm described in Fact 4, which proves that $\hat{E}v$ itself is useful, is a simple linear function of $\hat{E}$.

We also note an important interplay between the “lifted” nature of the SDP and the utility analysis of the exponential mechanism. On the one hand, the power of the SDP comes from lifting from the one-dimensional distribution to the lift $d + n$ variables $v, b$ to $(d + n + 1)^2$ variables, and solving a convex problem in the lifted space. On the other hand, for the exponential mechanism to satisfy utility with just $O(d)$ samples, it is important that we use it to sample from $d$ dimensions (where, in particular, there is a $\sqrt{O(d)}$ sized cover) rather than, say, $d^2$ dimensions. This tension is resolved by hiding the additional variables inside the optimization problem which defines $s$, so that exponential mechanism still samples from a $d$-dimensional distribution, but we can still use the power of SoS and semidefinite programming.

Lipschitzness The sampling algorithm of [9] (like other algorithms for sampling from log-concave probability distributions) runs in polynomial time in the ambient dimension, so long as the distribution has Lipschitz log-probabilities. Natural approaches to force
Together, these imply that $s(X, v_0)$ is Lipschitz with respect to $v_0$. To establish Lipschitzness, we make a two-step argument:

1. We show that dual solutions to the SDP defining $s(X, v_0)$ have optimal dual certificates which are not too large in norm. (At most, say, poly($d, n$).)

2. We show that any such dual solution to the SDP for $s(X, v_0)$ which certifies an upper bound of $c$ can be adapted to a dual solution for $s(X, v_0 + \Delta)$ which certifies an upper bound of $c + \|\Delta\| \cdot poly(d, n)$, for any small perturbation vector $\Delta$.

Together, these imply that $s(X, v_0)$ is poly($d, n$)-Lipschitz with respect to $v_0$. Since the Lipschitz constant only arises in our algorithm’s running time, this suffices for our purposes. This concludes our overview of the second phase of our private mean estimation algorithm.

3. PRELIMINARIES

3.1 SoS Proofs and Pseudoexpectations

We give a brief overview of SoS; for details see [7].

SoS Proofs. We first informally review the SoS proof system. Let $p(x_1, \ldots, x_m)$ be multivariate polynomials in indeterminates $x_1, \ldots, x_m$. The SoS proof system can prove statements of the form:

$$\text{For all } x \in \mathbb{R}^m, \text{ if } p_1(x) \geq 0, \ldots, p_m(x) \geq 0, \text{ then } p(x) \geq 0.$$ 

Polynomials are highly expressive, so a wide range of mathematical statements can be encoded in the above form. An SoS proof of such a statement is a family of polynomials $(g_s(x) : S \subseteq [m])$ such that each $g_s(x) = \sum_{i=1}^r q_s^{(i)}(x)^2$ is a sum of squares, and $p(x) = \sum_{S \subseteq [m]} g_s(x) \cdot \prod_{i \in S} p_i(x)$.

SoS proofs are duals to semidefinite programs arising from the Sum of Squares method, where pseudoexpectations are primal solutions. As in many applications of convex programming, to prove facts about primal solutions, the main technique is to construct duals. In particular, to show that the SoS SDPs we use for extremal mechanism score functions satisfy bounded sensitivity and privacy, it suffices to construct SoS proofs witnessing these facts.

Pseudoexpectations. For even $d \in \mathbb{N}$, a degree-$d$ pseudoexpectation in indeterminates $x = x_1, \ldots, x_n$ is a linear operator $E :
The algorithm produces a sample from a distribution \( D \) such that for every (measurable) \( S \subseteq C \),
\[
e^{-\epsilon} \Pr(A \in S) \leq \frac{\int \exp(f)}{\int \exp(f)} \leq e^{\epsilon} \Pr(A \in S).
\]

The algorithm runs in time \( poly(d, L \cdot \text{diam}(C), 1/\epsilon, \log \text{diam}(C)) \), making at most that many queries to the oracles.

[9] actually provides the running time bound \( poly(d, L \cdot \text{diam}(C), 1/\epsilon) \), but we can deduce the more precise bound in the theorem statement by a simple scaling argument. We note that recent work of [57] provides an algorithm which improves the running time’s dependence on \( 1/\epsilon \) from polynomial to poly-logarithmic, as well as reducing the polynomial dependence on \( d \) for convex sets \( C \) that contain a ball of radius \( r \), at an additional cost of \( \log(1/r) \) (Remark 2.5 of [57]). As our main focus is on providing polynomial time algorithms and not on designing the fastest algorithms, we do not further employ their improved methods.

### 4. META-THEOREM ON SOS EXPONENTIAL MECHANISM

To describe the SoS exponential mechanism more completely, we prove a meta-theorem on its performance. This meta-theorem could be extended in various ways, but the version we give here captures the mechanism as it is used in our paper. The reader interested solely in our result on mean estimation may comfortably skip this section as we do not rely on it elsewhere, but the exposition and abstraction here may make it easier to follow.

**Meta-theorem Setup.** Consider the following template to capture the exponential mechanism in the language of polynomials. Let \( X \) be a universe of possible datasets and \( C \subseteq \mathbb{R}^n \) be a set of candidates. Consider a score function of the following form. For each dataset \( X \), suppose there is a family of polynomials \( p^X_1, p^X_2, \ldots, p^X_m \) in variables \( x_1, \ldots, x_n, y_1, \ldots, y_N \), and the score function \( s(X, x) \) is given by
\[
s(X, x) = \max_y p^X(x, y) \text{ such that } p^X_1(x, y) \geq 0, \ldots, p^X_m(x, y) \geq 0.
\]

**Example 7 (Tukey depth with margin).** To make things a bit less abstract, let us see that a score function closely related to the Tukey depth is expressible in this form. Suppose \( X = X_1, \ldots, X_N \in \mathbb{R}^n \) is a dataset. Recall that the Tukey depth of a point \( z \in \mathbb{R}^n \) is given by the maximum number of \( X_i \)'s which lie on one side of a hyperplane through \( z \).

Later on, for a fixed \( z \in \mathbb{R}^n \) with \( \|z\| = 1 \), we will want to run the exponential mechanism to select a direction \( v \) such that many \( X_i \)'s lie above a hyperplane through \( z \) in direction \( v \), at distance at least \( r > 0 \) from that hyperplane, so our score function for \( v \) is the number of such \( X_i \)'s. We can express this as follows:
\[
s(X, v) = \max_{b_1, \ldots, b_N} \sum_{i=1}^N b_i \text{ s.t. for all } i, b_i^2 = b_i \text{ and } b_i(X_i - z, v) \geq b_i \cdot r.
\]
Indeed, approximation algorithms for finding such \( \nu \) play a key role in recent algorithmic advances in robust and heavy-tailed statistics.

Utility and Bounded Sensitivity in the Language of Polynomials

Utility in this framework takes exactly the same form as in the usual exponential mechanism – to demonstrate utility, one would show that high-scoring \( x \)'s are good, and there are not too many low-scoring \( x \)'s. The first of these statements is naturally expressible in the SoS proof system, and it turns out that the latter will not need to be expressed as an SoS proof. There is just one technical subtlety: the requirement that \( x \in C \), if it is used in the proof of utility, must be captured by the polynomials \( p_1(x, y) \geq 0, \ldots, p_m(x, y) \geq 0 \), as the SoS proof system has no other way of natively using the hypothesis that \( x \in C \). (We illustrate this in the example below.)

To formulate bounded sensitivity within SoS will take a little additional work – SoS will require for there to be a certain kind of witness to bounded sensitivity. This is not a major restriction, as natural proofs of bounded sensitivity for optimization-based score functions typically yield such witnesses anyway.

Making this concrete, a natural way to show that a score function like the above satisfies bounded sensitivity is to relate feasible solutions to the optimization problem for \( X \) to those for a neighboring dataset \( X' \), without losing too much in the objective value. Let us suppose that for each neighboring pair \( X, X' \) there is a transformation \( y'(y) \) such that for all \( x, y \), if \( y \) is feasible for \( X \) (i.e. \( p_1^X(x, y) \geq 0, \ldots, p_m^X(x, y) \geq 0 \)) then \( y'(y) \) is feasible for \( X' \) (i.e. \( p_1^{X'}(x, y'(y)) \geq 0, \ldots, p_m^{X'}(x, y'(y)) \geq 0 \)). If additionally \( p^X(x, y) - p^{X'}(x, y'(y)) \leq 1 \), this transformation (together with the corresponding one mapping \( y' \) to \( y \)) witnesses bounded sensitivity for \( s \). For technical reasons, our meta-theorem imposes the restriction that \( y' \) is a linear function of \( y \), but this still suffices for our algorithms.

Example 8 (Continuation of Example 7). First addressing utility: it turns out that the proof of utility for \( \nu \) having high score according to (2) will rely on \( \|\nu\| \leq 1 \). So we will have to strengthen our system of polynomials to include this constraint. As a technicality, we will also shift our objective function so that having positive score is good enough for utility:

\[
\max_{b, \nu} \sum_{i=1}^{N} b_i - 0.9N \text{ such that } b_i^2 = b_i, b_i(X_i - z, \nu) \geq b_i \cdot r, \|\nu\| \leq 1.
\]

(3)

Now, to establish bounded sensitivity, consider two neighboring datasets \( X = X_1, \ldots, X_N \) and \( X' = X'_1, X'_2, \ldots, X'_N \), where \( X \) and \( X' \) differ on the first vector. If \( (b, \nu) \) is a feasible solution to (3) for \( X \) with objective value \( t \), then we can replace it with \((0, b_2, \ldots, b_N, \nu)\) to get a feasible solution for \( X' \) with objective value at least \( t - 1 \). The meta-theorem requires there to be an SoS proof of this fact; this (easy) SoS proof was first established in [33].

Robustly Satisfiable Polynomials

Before stating our meta-theorem, we need one more technical definition, capturing a certain well-conditioned-ness property of a polynomial optimization problem. Ultimately, this condition will imply a Lipschitz property of semi-definite relaxations of that optimization problem. This Lipschitz property will be used, in turn, to bound the running time of MCMC-based samplers for probability densities using those semidefinite relaxations as log-probabilities.

The details of the following definition (Definition 9) may appear opaque, but they are not too important – a good intuitive interpretation is that the polynomial optimization problem

\[
\max_{x, y} p(x, y) \text{ s.t. } p_1(x, y) \geq 0, \ldots, p_m(x, y) \geq 0
\]

has a robust space of feasible solutions. Roughly, this means that for any \( x \) there is a small ball \( B \) around \( x \) such that for any \( x' \in B \) there is a feasible solution \( (x', y) \) whose objective value isn't too large. (The actual condition we use is slightly weaker than this.) This type of condition is common in meta-theorems involving the SoS proof system, to rule out the use of pathological \( p, p_1, \ldots, p_m \), and it is typically not too difficult to establish – see, e.g. [34, 66].

Definition 9 (Robustly satisfiable polynomial systems). Let \( C \subseteq \mathbb{R}^n \) and let \( p, p_1, \ldots, p_m \) be polynomials in \( x = x_1, \ldots, x_n \) and \( y = y_1, \ldots, y_N \). Let \( \eta > 0 \). Consider a family of optimization problems, one for each \( x \in C \), given by

\[
\max_{y} p(x, y) \text{ s.t. } p_1(x, y) \geq 0, \ldots, p_m(x, y) \geq 0.
\]

We say this family is \( \eta \)-robustly satisfiable if, for each \( x \in C \), each \( x' \) in the ball of radius \( \eta \) around \( x \) can satisfy the constraints. That is, for each \( x' \) such that \( |x' - x| \leq \eta \), there exists \( y \) such that \( p_1(x', y) \geq 0, \ldots, p_m(x', y) \geq 0 \).

Note that in our algorithms, \( \eta \) will factor only into running times and not sample complexity or accuracy guarantees, so rather coarse bounds on \( \eta \), perhaps loose by polynomial factors, suffice for our purposes.

Example 10 (Continuation of Examples 7, 8). Let us imagine now that \( C \) is a ball of radius 0.9 centered at the origin, to see a proof sketch of \( \eta \)-robust satisfiability for (3). For each \( v \in C \) and every vector \( \Delta \) with \( \|\Delta\| \leq 0.1 \), the constraints of (3) are satisfied by \( (v + \Delta, 0) \). So, (3) is \( \eta \)-well-conditioned for \( \eta = 0.1 \), with respect to \( C \).

With this setup in hand, we can state our meta-theorem.

Theorem 11 (Meta-Theorem on SoS Exponential Mechanism). Let \( C \subseteq \mathbb{R}^n \) be a compact, convex set and \( X \) a universe of possible datasets, equipped with a “neighbors” relation. Suppose that for every dataset \( X \) there exists an Archimedean and \( \eta \)-robustly satisfiable system of polynomial inequalities \( \mathcal{P}^X(x, y) = \{p_1^X(x, y) \geq 0, \ldots, p_m^X(x, y) \geq 0\} \) and a polynomial \( p^X(x, y) \), all of degree at most \( D \), in indeterminates \( x_1, \ldots, x_n, y_1, \ldots, y_N \) such that for every neighboring dataset \( X' \) there is a linear function \( y'(y) \) such that bounded sensitivity has an SoS proof:

\[
\forall j, \mathcal{P}^X(x, y) + \mathcal{P}^X(x, y) \cdot \deg(p_j^X) \cdot \mathcal{P}_j^{X'}(x, y'(y)) \geq 0
\]

and \( \mathcal{P}^X(x, y) + \mathcal{P}^X(x, y) - p^X(x, y) - p^X(x, y') \leq 1 \).

Suppose also that for every \( X \), there are SoS proofs \( \mathcal{P}^X(x, y) + \mathcal{P}^X(x, y) \leq 1/\eta \) and \( \mathcal{P}^X(x, y) + \mathcal{P}^X(x, y) \leq 1/\eta \). Furthermore, suppose that the polynomials \( \mathcal{P}^X \) and \( p^X \) and the polynomials used in the above SoS proofs, all have coefficients expressible in at most \( B \) bits.

Then for every \( \epsilon > 0 \) and \( D \in \mathbb{N} \) there exists an \( \epsilon \)-differentially private algorithm which takes as input the polynomials \( p^X, p_1^X, \ldots, p_m^X \) and \( B, \eta > 0 \), with the following guarantees:
Utility: For every $X$, if there is an SoS proof of utility for $X$ which is degree-$\deg(p)$ with respect to $p$, i.e.,
$$p^X(x, y) \cup \{p(x, y) \geq 0\} \vdash_{\deg(p)} \|x - x^*(X)\|^2 \leq \alpha^2$$
for some vector $x^*(X) \in \mathbb{R}^n$ and $\alpha > 0$, where the coefficients of all polynomials involved in the proof are expressible with $B$ bits, and if
$$\text{poly}(C) \leq r,$$
then the algorithm outputs $x$ such that $\|x - x^*(X)\| \leq \alpha + 2^{-B}$ with probability at least $1 - r \exp(-\Omega(ct))$.

Running time: The algorithm runs in time
$$\text{poly}(n^D, N^D, m^D, \frac{1}{\varepsilon}, \frac{1}{\eta}, \text{diam}(C), B),$$
making at most this many calls to membership and projection oracles for $C$.

4.1 Proof of Theorem 11

We describe the algorithm we use to prove Theorem 11; then we assemble the lemmas we need for the analysis.

SoSExponentialMechanism. Input: polynomials $p^X, p^X_1, \ldots, p^X_m$, $D \in \mathbb{N}, \eta > 0, B \in \mathbb{N}$. (1) For $x_0 \in C$, let
$$s(X, x_0) = \max_{\tilde{E}} \tilde{E}p^X(x, y) \text{ such that } \deg \tilde{E} = D,$$
where the optimization is over $\tilde{E}$ in indeterminates $x, y$. (2) Let $B' = B + T(\text{diam}(C), 1/\eta, 1/\varepsilon, d)$, where $T$ is a sufficiently-large polynomial in the running time of the log-concave private sampler of [9], when run with finite-precision arithmetic. (3) Run the log-concave private sampling algorithm of [9] (Lemma 6.5) with score function $s$, Lipschitz parameter $\text{poly}(1/\eta)$, and privacy parameter $\varepsilon/4$. Whenever the sampling algorithm makes a call to $s(X, x_0)$, solve the underlying SDP to poly($B'$) bits of precision.

Theorem 11 is immediate from the following lemmas, all of which we establish in the next section.

Lemma 12 (High-scoring $x_0$ is found in polynomial time). Given the setup of Theorem 11, for all $X$, if
$$\text{poly}(C) \leq r,$$
then with probability at least $1 - r \exp(-\varepsilon(t/2 - 1))$, the $x_0$ output in step (2) of SoSExponentialMechanism has $s(X, x_0) \geq 0$.

Lemma 13 (High-scoring $x_0$ is useful). Under the assumptions of Theorem 11, for all $X$, if there is an SoS proof of utility for $X$ as described in Theorem 11, then for all $x_0$ such that $s(X, x_0) \geq 0$, $\|x^*(X) - x_0\| \leq \alpha + 2^{-B}$.

Lemma 14 (Privacy). Under the assumptions of Theorem 11, SoSExponentialMechanism satisfies $\varepsilon$-DP.

4.2 Proofs of Lemmas

We will prove Lemmas 12, 13, and 14.

Remark on numerical issues: Because of the choice of $B'$, the guarantees of the log-concave sampling algorithm will apply equally well if it receives $s(X, x_0) \pm 2^{-B'}$ as if it receives $s(X, x_0)$ when making oracle calls to $s$. (Given its running time, it cannot even read enough bits to tell the difference.) So, we will henceforth ignore the difference and presume that the log-concave sampler observes the values $s(X, x_0)$ exactly.

The first step is to establish that the target probability distribution is actually log-concave and Lipschitz, so that we can use the guarantees of [9].

Lemma 15. For all $X$, the function $s(X, x_0)$ is concave in $x_0$.

Proof. Consider $x_0$ and $x_0'$ and let $\tilde{E}$ be the optimal solution to the optimization problem defining $s(X, x_0)$ and similarly for $\tilde{E}'$ and $s(X, x_0')$. Then $\frac{1}{2} \tilde{E} + \frac{1}{2} \tilde{E}'$ is feasible for $s(X, \frac{1}{2} x_0 + \frac{1}{2} x_0')$. So $s(X, \frac{1}{2} x_0 + \frac{1}{2} x_0') \geq \frac{1}{2} s(X, x_0) + \frac{1}{2} s(X, x_0')$.

Lemma 16 (Robustly satisfiable systems yield Lipschitz SDPs). Given the setup in Theorem 11, for all $x_0, x_0' \in C$ and all $X$, we have $|s(X, x_0) - s(X, x_0')| \leq \max(1/\eta, \|x_0 - x_0'\|)$.

Proof. As shorthand, let us write $s = s(X, x_0)$. Since $p^X$ is Archimedean, we can apply standard pseudoeffectivity/SoS proof duality to conclude that for every $\varepsilon > 0$ there is a polynomial identity in variables $x, y$:
$$s + \varepsilon - p^X(x, y) = \sum_{\lambda \in [m]} q_{\lambda}(x, y) \prod_{i \in S} p_{i}^X(x, y) + (\lambda, x - x_0),$$
where $q_\lambda$ are SoS polynomials, all the terms above have degree at least $D$, and $\lambda \in \mathbb{R}^n$ is a vector.

Our first goal is to bound $\|\lambda\|$. By robust satisfiability, if we let $x' = x_0 + \eta \frac{\lambda}{\|\lambda\|}$, there exists $y'$ such that $p_\lambda^X(x', y') \geq 0$ for all $i$. Hence,
$$s + \varepsilon - p^X(x', y') \geq \eta \|\lambda\|.$$
Since there are SoS proofs that $p^{X}(x, y) \leq 1/\eta$ and $-p^{X}(x, y) \leq 1/\eta$, and we can take $|\varepsilon| \leq 1/\eta$, the left-hand side is $O(1/\eta^2)$, so we find $\|\lambda\| \leq O(1/\eta^2)$.

We claim that $s(X, x_0') \leq s + O(1/\eta^2) \cdot \|x_0 - x_0'\|$. To see this, note that for each $\varepsilon > 0$, we can write
$$s + \varepsilon + \lambda_0 - x_0 - x_0') - p^X(x, y) = \sum_{\lambda \in [m]} q_{\lambda}(x, y) \prod_{i \in S} p_{i}^X(x, y) + (\lambda, x - x_0'),$$
which, after Cauchy-Schwarz, certifies the upper bound $s + \varepsilon + \|\lambda\| \|x_0 - x_0'\|$ on $s(X, x_0')$. Since this works for all $\varepsilon > 0$, we find $s(X, x_0') \leq s + O(1/\eta^2) \|x_0 - x_0'\|$.

As a corollary of Lemmas 15 and 16, combined with Lemma 6.5 of [9], we obtain:

Corollary 17. Given the setup of Theorem 11, for every $X$, the output of step (3) of SoSExponentialMechanism is a sample from a distribution $D_X$ supported on $C$ such that for every event $A$
$$e^{-\varepsilon/2} \mathbb{P}_{D_X}(A) \leq \mathbb{P}_{\tilde{D}_X}(A) \leq e^{\varepsilon/2} \mathbb{P}_{D_X}(A)$$
where $D_{\text{target}}^X$ is the distribution with density proportional to $\exp((r/2)s(X, x_0))$. Furthermore, the sampler runs in time at most $\text{poly}(1, \frac{1}{\varepsilon}, \frac{1}{\eta}, \text{diam}(C))$, making at most that many calls to a membership oracle for $C$ and to an evaluation oracle for $s(X, \cdot)$.

4.2.1 Privacy: proof of Lemma 14.

**Lemma 18.** Given the conditions of Theorem 11, the score function $s$ has sensitivity at most $1$.

Proof. Let $X, X'$ be neighboring datasets, and let $\hat{E}$ be an optimal solution to the optimization problem defining $s(X, x_0)$. We will construct a feasible solution $\hat{E}'$ for $s(X', x_0)$ whose objective value is at most $s(X, x_0) + 1$. Since we could swap $X$ and $X'$, this will prove that $|s(X, x_0) - s(X', x_0)| \leq 1$.

For any degree $D$ polynomial $f$, we define $\hat{E}' f(x, y) = \hat{E} f(x, y'')$. Note that the degree of $\hat{E}'$ as a pseudoeffectuation is the same as that of $\hat{E}$, because $y''$ is linear.

We claim that $\hat{E}'$ is feasible for $s(X', x_0)$. Clearly $\hat{E}' x = x_0$, so we just need to check that $\hat{E}'$ satisfies $P^X$. For each $j$, we check that $\hat{E}'$ satisfies $P^X_j (x, y) \geq 0$. Consider any square polynomial $q$ such that $\deg(q \cdot P^X) \leq D$. We need to show $\hat{E}' q \cdot P^X_j \geq 0$.

Using the SoS proof $P^X(x, y) \cdot \deg(P^X_j) P^X_j (x, y'')$, we can write

$$q(x, y'') \cdot P^X_j (x, y'') = q(x, y') \cdot \sum_{S \subseteq \{m\}} q_S(x, y) \prod_{i \in S} P^X_i (x, y)$$

where every term in the sum on the right-hand side has degree at most $\deg(P^X_j)$. Therefore, for every $S$, we have

$$q(x, y') \cdot q_S(x, y) \prod_{i \in S} P^X_i (x, y)$$

has degree at most $D$. So, applying $\hat{E}'$ to both sides, we find that $\hat{E}' q \cdot P^X_j \geq 0$, using that $\hat{E}'$ satisfies $P^X$.

Finally, we have to check that $\hat{E} P^X(x, y) - \hat{E}' P^X (x, y) \leq 1$. We expand the definitions and use our SoS proof of bounded sensitivity.

$$\hat{E} P^X(x, y) - \hat{E}' P^X (x, y) = \hat{E} P^X(x, y) - \hat{E} P^X (x, y') \leq 1.$$

□

Proof of Lemma 14. By Lemma 18 and the usual analysis of the exponential mechanism, an output from the target distribution $D_{\text{target}}^X$ from Corollary 17 would satisfy $\varepsilon/2$-DP. Since, according to Corollary 17, the actual distribution output by step (3) of the algorithm differs only by multiplicative $e^{\varepsilon/2}$, the output of the log-concave sampler satisfies $\varepsilon$-DP.

4.2.2 Utility: proofs of Lemmas 12 and 13.

Proof of Lemma 12. By the standard analysis of the exponential mechanism, a sample from $D_{\text{target}}^X$ (as described in Corollary 17) would output $x_0$ with $s(X, x_0)$ probability at least $1 - \exp(-rt/2)$. Since the actual output distribution of step (3) is $e^{\varepsilon/2}$ multiplicatively close to this, we are done.

Proof of Lemma 13. Since $x_0$ has $s(X, x_0) \geq 0$, there exists $E$ of degree $D$ satisfying $P^X_j (x, y) \geq 0, \ldots, P^X_j (x, y') \geq 0$ and having $E x = x_0$ and $E P^X (x, y) \geq 2^{\varepsilon/2}$-poly($B$). Then applying $E$ to either side of the SoS proof of utility, we obtain $E|x - x^*(X)|^2 \leq \alpha^2 + 2^{\varepsilon/2}$-poly($B$).

By convexity, $|E x - x^*(X)| \leq \alpha + 2^{\varepsilon/2}$-poly($B$), so we are done. □

ACKNOWLEDGMENTS

The authors would like to thank Adam Smith for his role in the conception and contributions in the early stages of this project.
