Abstract
We investigate the general geometric properties of the surface of infinite redshift corresponding to the event horizon of the static and axisymmetric solution of the Einstein vacuum equations, which only possesses mass $M$ and quadrupole moment $Q$. The deformation of the Schwarzschild surface $r = 2M$ produced by the quadrupole moment is shown, and the range of values of this multipole moment is specified, which preserves a regular, closed, continuous and differentiable surface. Some thermodynamic consequences and speculations ensuing from our results are discussed.

1. Introduction

As is well known [1], the only static and asymptotically flat vacuum spacetime possessing a regular horizon is the Schwarzschild solution. All the other Weyl exterior solutions [2–6] exhibit singularities in the physical components of the Riemann tensor at the horizon.

For not particularly intense gravitational fields and small fluctuations, deviations from spherical symmetry may be described as perturbations of the Schwarzschild exact solution [7].

However, such a perturbative scheme will eventually fail in regions close to the horizon (although strictly speaking the term ‘horizon’ refers to the spherically symmetric case, we shall use it when considering the $r = 2M$ surface, in the case of small deviations from...
sphericity). Indeed, as we approach the horizon, any finite perturbation of the Schwarzschild spacetime becomes fundamentally different from the corresponding exact solution representing the quasi-spherical spacetime, even if the latter is characterized by parameters whose values are arbitrarily close to those corresponding to the Schwarzschild metric [8–12]. This, of course, is just an expression of the Israel theorem (for observational differences between black holes and naked singularities see [13, 14] and references therein).

Therefore, for strong gravitational fields, no matter how small the multipole moments of the source are (those higher than monopole), there exists a bifurcation between the perturbed Schwarzschild metric and all the other Weyl metrics (in the case of gravitational perturbations).

Examples of such a bifurcation have been brought out for the $\gamma$ metric [15–23] and for the spacetime possessing only monopole and quadrupole moments (hereafter $M–Q$ spacetime [24–26]) in the study of the trajectories of test particles for orbits close to $r = 2M$ [27, 28].

The influence of the quadrupole moment on the motion of test particles within the context of the Erez–Rosen metric [29] has been investigated by many authors (see [30–33] and references therein).

The purpose of this paper is to study further the properties of the $M–Q$ spacetime in order to bring out the bifurcation mentioned above and to contrast our results with those obtained for other Weyl metrics.

The rationale for the choice of the $M–Q$ spacetime is based on the fact that its relativistic multipole structure (particularly that of a sub-class of this solution $M–Q^{(1)}$ [24], which, being an exact solution, corresponds to the first order in quadrupole moment in $M–Q$) may be interpreted as a quadrupole correction to the Schwarzschild spacetime, and therefore represents a good candidate among the known Weyl solutions, to describe small deviations from spherical symmetry.

In this paper, we shall see that unlike in the $\gamma$-metric [23], the area does not vanish at the horizon. However, the surface gravity diverges as is the case for the $\gamma$-metric [34]. We shall calculate explicitly the surface of infinite redshift corresponding to the $M–Q$ spacetime and determine the range of values of the quadrupole moment for which such a surface is close, continuous and differentiable. Next, we shall calculate the surface gravity, which exhibits a singularity along the symmetry axis as we approach the event horizon. Some thermodynamic consequences derived from these results are discussed.

2. The $M–Q$ solution

In [35], a so-called multipole symmetry adapted (MSA) coordinate system was defined, which allows us to write the $g_{tt}$ metric component of pure multipole solutions in general relativity, in a form resembling the classical multipole potential. The existence of such a type of coordinate system was proved in [35]. The relation between the MSA system of coordinates $(r, y \equiv \cos \theta)$ and the Weyl standard coordinates $(R, \omega \equiv \cos \theta)$ is given by the following expression:

\begin{align}
  r &= R \left[ 1 + \sum_{n=1}^{\infty} f_n(\omega) \frac{1}{R^n} \right] \\
  y &= w + \sum_{n=1}^{\infty} g_n(\omega) \frac{1}{R^n},
\end{align}

with $f_n(\omega)$ and $g_n(\omega)$ being the polynomials in the angular variable $\omega$ explicitly calculated in [35], where the consistency of this expansion and the convergence of the series is discussed. In particular, for the case of the solution with a finite number of multipole moments given by the monopole and the quadrupole moments, the corresponding MSA coordinates can be written...
as follows:
\[
r = r_s \left[ 1 - q P_2(y_s) \lambda_s^3 - \frac{q}{28} \left( 35 y_s^4 + 6 y_s^2 - 9 \right) \lambda_s^4 \\
- \lambda_s^5 \left( \frac{q}{28} \left( 105 y_s^4 - 66 y_s^2 + 1 \right) - q^2 \left( 12 y_s^4 - 9 y_s^2 + 1 \right) \right) + \cdots \right]
\]
\[
y = y_s \left[ 1 - (1 - y_s^2) \left( q \lambda_s^3 + \frac{5q}{28} \left( 7 y_s^2 + 9 \right) \lambda_s^4 \\
+ \frac{q}{35} \lambda_s^5 \left( (175 y_s^4 + 57) + q \left( 126 - 336 y_s^2 \right) \right) + \cdots \right] \right),
\]
(2)

where \( P_n(y) \) stands for the Legendre polynomials; \( r_s \) and \( y_s \) denote the standard Schwarzschild coordinates; \( \lambda_s \equiv M/r_s \); and \( q \equiv Q/M^3 \) (\( Q \) stands for the quadrupole moment).

The relevance and the physical and mathematical interest of these systems of coordinates become evident from the fact that they are related with the existence of certain symmetries of the static and axisymmetric vacuum field equations, which generalize the action of those symmetry groups on the classical equations [36]. For the monopole solution (spherical symmetry), the MSA system of coordinates is exactly the standard Schwarzschild coordinate, and the associated symmetry group of the field equations allow us to determine univocally the system of coordinates by means of solving a certain Cauchy problem. In a recent work [37], the MSA system of coordinates has been used to calculate relativistic corrections of the perihelion advance for orbital test particles.

The \( M–Q \) solution of the static and axisymmetric vacuum equations (see [37, 24]) can be written in the corresponding MSA system of coordinates \( \hat{x} \equiv (r, y) \) as follows:

\[
g_{rr}(\hat{x}) = -1 + 2 \left[ \hat{\lambda} + \frac{Q}{M^3} \hat{\lambda}^3 P_2(y) \right]
\]
\[
g_{rr}(\hat{x}) = \frac{1}{1 - 2\hat{\lambda}} \left[ 1 + (1 - 2\hat{\lambda}) \sum_{i=3}^{\infty} \hat{\lambda}^i U_i(y, Q) \right]
\]
\[
g_{yy}(\hat{x}) = \frac{1}{1 - y^2 \hat{\lambda}^2} \left[ 1 + \sum_{i=3}^{\infty} \hat{\lambda}^i D_i(y, Q) \right]
\]
\[
g_{\phi\phi}(\hat{x}) = (1 - y^2) \frac{M^2}{\hat{\lambda}} \left[ 1 + \sum_{i=3}^{\infty} \hat{\lambda}^i T_i(y, Q) \right],
\]
(3)

where \( \hat{\lambda} \equiv M/r \), and \( U_i, D_i \) and \( T_i \) denote the polynomials in the angular variable \( y \) of even order depending on the quadrupole moment \( Q \). The explicit form of some polynomials are given in [37].

3. The event horizon

In this work, we want to make use of the MSA system of coordinates to calculate the event horizon of the exact monopole–quadrupole solution of the static and axisymmetric vacuum Einstein equations.

In MSA coordinates, the \( g_{00} \) metric component of the \( M–Q \) solution takes the form
\[
g_{00} = -1 + 2V(r, y),
\]
(4)

with \( V(r, y) = \frac{M}{r} + \frac{Q}{28} P_2(y) \), which is a reminiscence of the classical multipole potential but now constructed with the relativistic monopole moment \( M \) and the quadrupole moment \( Q \), respectively. The event horizon of this static solution is given by the equipotential surface \( V(r, y) = \beta \), with \( \beta = 1/2 \). Equivalently, the surface of infinite redshift defined by the
condition $g_{tt} \equiv \xi^a \xi_a = 0$ ($\xi^a$ being the time-like Killing vector) can be calculated by solving the following algebraic equation:

$$r^3 - 2M r^2 - 2 Q P_2(y) = 0. \quad (5)$$

Therefore, the appropriate root of this equation is a function $r = r(y)$, which represents the generatrix curve of revolution surface describing the event horizon of the axisymmetric solution. Let us note that this curve is symmetric with respect to the equatorial plane due to the symmetry of the solution, and therefore, the study of $r = r(y)$ can be restricted to the value of $y \in (0,1)$, or equivalently the angular coordinate $\theta \in (0, \pi/2)$.

In order to determine the real roots of this third-degree algebraic equation, we must define the different domains of the equation in terms of the values for $y = \cos \theta$. It depends on the value of the quantity

$$d = q P_2(y) \left( q P_2(y) + \frac{16}{27} \right) = a(a + 2\alpha), \quad (6)$$

with the notation $a \equiv q P_2(y)$, $\alpha \equiv 8/27$ and $q \equiv Q/M^3$, as follows:

- **DI**: $d < 0$, $a \in (-2\alpha, 0)$,
- **DII**: $d > 0$, $a \in (-\infty, -2\alpha) \cup (0, \infty)$, \quad (7)
- **DIII**: $d = 0$, $a = -2\alpha$, $a = 0$.

The region defined by DI leads to three real roots of the algebraic equation (5), as well as the region DIII (where at least two of these roots are equal), whereas region DII provides only one real root.

Let us first analyze the region DIII: the solutions of the algebraic equation for this region are the following:

$$r_{d=0}(y) \equiv r_1(y) = 2M \left[ \frac{1}{4} + (a + \alpha)^{1/3} \right],$$

$$r_{d=0}(y) \equiv r_{2,3}(y) = 2M \left[ \frac{1}{4} - \frac{1}{2}(a + \alpha)^{1/3} \right]. \quad (8)$$

It is easy to show that we have positive real roots leading to a good matching with the region DII only if $a = 0$, which corresponds to the angular value $y^0_1 = 1/\sqrt{3}$: the other possible point of this region is $y^0_2 = y^0_1 \sqrt{1 - 4\alpha/q}$, which corresponds to the condition $a = -2\alpha$, as can be seen from figure 1. However, the roots for that value are

$$r_1(y^0_2) = -\frac{2M}{3}, \quad r_{2,3}(y^0_2) = \frac{4M}{3}, \quad (9)$$

and they only match with the unique real root for the region DII ($d > 0$) providing a negative value of the curve:

$$r_{d=0}(y) = M \left[ (a + \alpha + \sqrt{3})^{1/3} + (a + \alpha - \sqrt{3})^{1/3} + \frac{2}{3} \right], \quad r_{d=0}(y^0_2) = -\frac{2M}{3}. \quad (10)$$

Therefore, we must limit the value of the parameter $q$ within the range $-2\alpha < q < 4\alpha$, where the value of $y^0_2$ is not real, to preserve the continuity of the curve $r = r(y)$.

Next, as indicated in (7), the region DII ($d > 0$) splits into two different open intervals given by the conditions $a > 0$ and $a < -2\alpha$. The condition $a > 0$ leads to $y < y^0_1$ (for $q < 0$) or $y > y^0_1$ (for $q > 0$), whereas the condition $a < -2\alpha$ cannot be fulfilled if the regularity range of the parameter $q \in (-2\alpha, 4\alpha]$ holds.

Hence, we can conclude that the different domains for the evaluation of the real roots of (5) are given by

$$q \in (0, 4\alpha] \begin{cases} 
   d > 0 & y > y^0_1 \\
   d = 0 & y = y^0_1 \\
   d < 0 & y < y^0_1 
\end{cases} \quad (11)$$
Figure 1. (a) The Legendre polynomial of degree 2 in the variable \( y \equiv \cos \theta \). (b) The function \( d = d(a) \) in terms of \( a \) (6). The two points, where \( d \) vanishes, are \( a = 0 \) and \( a = -2\alpha \) (\( \alpha = 8/27 \)).

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)

Finally, the region DI \((d < 0)\) has the following three real roots:

\[
q \in (-2\alpha, 0) : \begin{cases} 
  d > 0 & y < y_0^1 \\
  d = 0 & y = y_0^1 \\
  d < 0 & y > y_0^1
\end{cases}.
\]  

(12)
Let us note that the continuous curve \( r = r(y) \) must be a piecewise-defined function since \( \kappa \) is not defined for the region \( d > 0 \) DII, where \( a > 0 \). Nevertheless, it can be shown that functions \( r_{d<0} \) and \( r_{d>0} \) are equivalent since we can rewrite \( r_{d<0} \) (13) by taking into account that
\[
\cos \kappa = 1 + \frac{a}{\alpha} \Leftrightarrow \cos \frac{\kappa}{3} = \frac{1}{2\sqrt{d}}[(a + \alpha + \sqrt{d})^{1/3} + (a + \alpha - \sqrt{d})^{1/3}]
\]
and therefore
\[
r_{d<0}(y) = M \left[ (a + \alpha + \sqrt{d})^{1/3} + (a + \alpha - \sqrt{d})^{1/3} + \frac{a}{\alpha} \right]
\]
which represents the root \( r_{d<0} \).

Finally, we can prove that the surface of the event horizon defined by the generatrix curve (15)–(16) is class \( C^1 \), i.e. \( r(y) \) is differentiable and the derivative is continuous. The derivative of the generatrix curve (15)–(16) with respect to the angular parameter \( \theta \) is given by the following expressions:
\[
\frac{dr_{d<0}}{d\theta} = -\sqrt{1 - y^2} 4M qy \sin \frac{\kappa}{3},
\]
\[
\frac{dr_{d>0}}{d\theta} = -\sqrt{1 - y^2} \frac{qM y}{\sqrt{d}} [(a + \alpha + \sqrt{d})^{1/3} - (a + \alpha - \sqrt{d})^{1/3}],
\]
and the continuity of the derivative at the boundary \((y = y_i)\) is fulfilled:
\[
\left. \frac{dr_{d<0}}{dy} \right|_{y=y_i} = \lim_{\alpha \to 0} \frac{4M qy}{3 \sqrt{-d}} \sin \frac{\kappa}{3} = \frac{3qM}{2\sqrt{3}}
\]
\[
\left. \frac{dr_{d>0}}{dy} \right|_{y=y_i} = \lim_{\alpha \to 0} \frac{qM y}{\sqrt{d}} [(a + \alpha + \sqrt{d})^{1/3} - (a + \alpha - \sqrt{d})^{1/3}] = \frac{3qM}{2\sqrt{3}}.
\]
In addition, for any value of the parameter \( q \) within the range considered \((-2\alpha, 4\alpha)\), the derivative of the curve \( r = r(y) \) is also continuous at the points intersecting the symmetry axis \( y = \pm 1 \), as well as at the equatorial plane \((y = 0)\), since both derivatives of \( r_{d<0} \) and \( r_{d<0} \) are zero at those points.

Hence, the surface of the event horizon is continuous and differentiable everywhere for the range of values of the quadrupole moment \( Q \in M^3 (-2\alpha, 4\alpha) \). Figures 2–4 show different aspects of the generatrix curve as well as the surface of the event horizon.

It should be observed that although pathological behavior might be expected for large (absolute) values of the quadrupole moment, it is not clear why such a behavior appears outside the range established above. We currently do not know if there is any physical significance behind that range.

4. The Area

The area of the event-horizon surface \( r = r(y) \) for the \( M-Q \) solution is given by the following expression:
\[
A = \int_0^{2\pi} \int_{-1}^{1} \sqrt{\hat{g}_{yy} \hat{g}_{\varphi\varphi}} \, dy \, d\varphi,
\]
where
\[
\hat{g}_{yy} = g_{rr} \left( \frac{dr(y)}{dy} \right)^2 + g_{yy},
\]
and \( g_{rr}, g_{yy} \) and \( g_{\varphi\varphi} \) are the metric components of the \( M-Q \) solution given by expressions (3) in the corresponding MSA system of coordinates. As we have previously seen, the event horizon
Figure 2. Generatrix curve $r = r(y)$, except for a factor $1/M$, in polar coordinates, for different positive values of $q$. The vertical axis $\bar{Z}$ represents the symmetry axis $y = \pm 1$, whereas the horizontal abscissa axis $\bar{X}$ represents any one direction on the equatorial plane orthogonal to $\bar{Z}$. The curve for each value of $q$ is drawn in different color depending on the corresponding domain up or down the boundary value $y = y_0^1$, where all different curves are crossing each other.

Figure 3. The whole curve $r(y)/M$ for all values of the angular polar coordinates and different values of $q$ ($q = 0$, $q = 1.08518$ and $q = -0.53518$). The curve with points represents the event horizon for the spherical symmetry case.

for the non-spherical case depends on the angular variable $\theta$ ($\cos \theta = y$) for the range defined in (15)–(16), and hence, its derivative with respect to the variable $y$ is different from zero.
Nevertheless, if we expand the expressions of the surface (15)–(16) as well as its derivative (19) in terms of the quadrupole parameter $q$, we obtain

$$r(y) \simeq 2M \left(1 - q^2 \frac{P_2(y)^2}{8\alpha}\right) + O(q^3)$$

$$\left(\frac{dr(y)}{dy}\right)^2 \simeq q^3 \frac{M^2 P_2(y)^2 y^2}{3\alpha^2} + O(q^4),$$

and we could approximate the event horizon to be equal to the Schwarzschild surface $r \simeq r_s = 2M$ and $\frac{dr}{dy} \simeq 0$, since we are interested in the behavior of the area for very slight deviations from spherical symmetry. Equivalently, we can say that $r(y) = 2M + \epsilon$, where $\epsilon \equiv \frac{2}{3}M(-1 + \cos \frac{\kappa}{3})$ represents the difference between the event horizon of the $M–Q$ solution and the corresponding surface in the spherical case, is a small quantity of order $q^2$.\(^5\)

Therefore, the area of the event horizon could be defined as follows:

$$A \simeq 2\pi \int_{-1}^{1} \sqrt{\gamma_{yy}\gamma_{z\psi}} \, dy.$$ (24)

Since we want to know how different is the area of the event horizon for the non-spherical case for slight deviations with respect to the Schwarzschild spacetime, let us consider the $M–Q^{(1)}$ solution.

$M–Q^{(1)}$ is a subclass of the $M–Q$ solution that represents a small deformation of Schwarzschild for a small parameter $q$. In fact, the $M–Q^{(1)}$ solution corresponds to the first order in the parameter $q$ in an expansion of the solution $M–Q$ in power series of that parameter.

When written in prolate spheroidal coordinates $\{x, y\}$, the event horizon is defined by $x = 1$ ($r = r_s = 2M$) if $q \leq 8/5$, and metric functions of the solution are

$$e^{-2\Psi} \simeq \left(\frac{x + 1}{x - 1}\right)^A e^B + O(q^2),$$

$$e^{2\gamma} \simeq \frac{x^2 - 1}{x^2 - y^2} \left(\frac{x - 1}{x + 1}\right)^C e^D + O(q^2),$$

where

$$A = 1 + \frac{5}{4} q \left(-1 + \frac{(3y^2 - 1)(3x^2 - 1)}{4}\right).$$

\(^5\) It can be seen from figures 2 and 3 that $\frac{\kappa}{3} = 2 + p$, where $p \equiv \epsilon / M$ with $-2/3 \leq p \leq 1/3$, and $p = 0$ for $q = 0$ leading to $r(y) = 2M$.\(^8\)
\[ B = -\frac{5}{8} q x \left( -\frac{4}{x^2 - y^2} + 3(3y^2 - 1) \right), \]
\[ C = -\frac{15}{4} qx(1 - y^2), \]
\[ D = -\frac{15}{2} q(1 - y^2) - \frac{5}{2} q(x^2 + y^2) \frac{1 - y^2}{(x^2 - y^2)^2}, \]

and the terms of order higher than \( q \) have been neglected.

The area of the event horizon is
\[ A = \lim_{x \to 1} M^2 \int_0^{2\pi} \int_{-1}^1 e^{-2\Phi} \sqrt{e^{2\gamma} (x^2 - y^2)(x^2 - 1)} \, dy \, d\varphi, \]

or, using (25) and (26)
\[ A = 2\pi M^2 \lim_{x \to 1} \int_{-1}^1 (x + 1)^{1-(C/2-A)} (x - 1)^{1+(C/2-A)} e^{B+D/2} \, dy. \]

Then, taking into account that
\[ \lim_{x \to 1} (x + 1)^{1-(C/2-A)} = 4, \quad \lim_{x \to 1} (x - 1)^{1+(C/2-A)} = 1, \]

we have that
\[ A \simeq 2\pi 4M^2 \int_{-1}^1 e^{-\frac{5}{8} q(1+3y^2)} \, dy, \]

which evaluated up to order \( q \) produces
\[ A \simeq 4\pi (4M^2) \left( 1 - \frac{5}{4} q \right) + O(q^2). \]

In the spherically symmetric case, the above expression brings us back to the well-known result
\[ A_{Sch.} = 16\pi M^2. \]

5. The surface gravity

The surface gravity \( k \) may be defined from the time-translation Killing vector \( \xi \)
\[ k^2 \equiv -\frac{1}{2} (\nabla_\mu \xi_\nu) \, (\nabla^\mu \xi^\nu). \]

In a static, asymptotically flat spacetime, it is the acceleration of a static observer near the horizon, as measured by a static observer at infinity.

Also, it may be defined more generally for any surface outside the horizon in terms of the four-velocity of a fiducial observer at rest with respect to the frame for which our metric functions are defined [38]. At the event horizon of course both definitions coincide.

For the case of a static and axisymmetric line element (diagonal matrix), the surface gravity \( k \) is given by the following expression:
\[ k = \sqrt{-\frac{1}{4} g^{00} g^{\nu \mu} \left( \frac{\partial g_{00}}{\partial x^\nu} \right)^2}, \]

where the index \( i = 1, 2 \) sums for the non-axial coordinates.

By taking into account expression (4), we have that
\[ \partial_r g_{00} = 2 \left( -\frac{M}{r^2} - \frac{3}{r^4} Q P_2(\cos \theta) \right), \]
\[ \partial_\vartheta g_{00} = -\frac{Q}{r^4} 6 \cos \theta \sin \theta, \]

and the terms of order higher than \( q \) have been neglected.
and therefore, the surface gravity for the $M$–$Q$ solution at the event horizon is given by the following expression:

$$
k = \hat{\lambda}^2 \frac{\sqrt{2}}{M \sqrt{1 - 2\hat{\lambda} - 2\hat{\lambda}^3 q P_2(y)}} \left[ \frac{(1 - 2\hat{\lambda})(1 + 3q\hat{\lambda}^3 P_2(y))^2}{1 + (1 - 2\hat{\lambda})U} + \frac{9\hat{\lambda}^4 q^2 y^2 (1 - y^2)}{1 + D} \right]^{1/2}, \quad (36)$$

where $\hat{\lambda} \equiv M/r$, and $U$ and $D$ denote the series appearing at the metric functions $g_{rr}$ and $g_{yy}$, respectively, which are given by expressions (3).

In the spherical case, we have $q = 0$, $D = 0$ and $U = 0$ producing

$$
k = \frac{\hat{\lambda}^2}{M}, \quad (37)$$

which at the event horizon $r = 2M (\hat{\lambda} = 1/2)$ leads to the well-known expression for the surface gravity of the Schwarzschild spacetime:

$$
k_{\text{Sch}} = \frac{1}{4M}. \quad (38)$$

Let us now calculate the surface gravity for the $M$–$Q$ solution by considering the event horizon $r(y)$ as an small deviation with respect to the Schwarzschild surface $r = 2M$ as follows:

$$
g_{00} = -\frac{e^{2\Psi}}{y^2},
\quad g_{rr} = M^2 e^{-2\phi} \frac{x^2 - y^2}{x^2 - 1},
\quad g_{yy} = M^2 e^{-2\phi} \frac{1 - y^2}{1 - y^2}, \quad (40)$$

from which it follows at once,

$$
g_{00}^\mu \frac{\partial g_{00}}{\partial x^\mu} = -\frac{e^{4\Psi - 2\phi}}{M^2 (x^2 - y^2)} [(x^2 - 1)X^2 + (1 - y^2)Y^2], \quad (41)$$

where the following notation has been introduced:

$$
X = A_1 \ln \left( \frac{x - 1}{x + 1} \right) - B_2 + \frac{2A}{x^2 - 1},
\quad Y = A_2 \ln \left( \frac{x - 1}{x + 1} \right) - B_3. \quad (42)
$$

In the spherical case ($q = 0$), as we approach the event horizon ($x \rightarrow 1$), we have

$$
X = \frac{2}{x^2 - 1}, \quad Y = 0, \quad (43)
$$

producing with (34)

$$
k_{\text{Sch}} = \frac{1}{4M}. \quad (44)$$
If we now consider the parameter $q$ to be arbitrarily small but non-vanishing, then from (41) we obtain
\[
X^2 \approx \frac{4}{(x^2 - 1)^2} + \frac{15}{x^3 - 1} \left[ \frac{3y^2 - 1}{x^2 - 1} + \frac{x(3y^2 - 1)}{2} \ln \left( \frac{x - 1}{x + 1} \right) \right] + \frac{1}{6} \left[ -\frac{4}{1 - y^2} + \frac{8}{(1 - y^2)^2} + 3(3y^2 - 1) \right] + O(q^2),
\]
\[
Y^2 \approx O(q^2),
\]
and therefore, the surface gravity for the $M$-$Q_{(1)}$ solution is given by the following expression:
\[
k \approx \frac{1}{4M} \left[ 1 + \frac{5}{8}q(1 - 15y^2) + \Lambda \right] + O(q^2),
\]
where
\[
\Lambda \equiv \frac{5}{2} q \lim_{x \to 1} \left( x - 1 \right) \left[ \frac{y^2 + 1}{(1 - y^2)^2} \right].
\]
The important point is that everywhere outside the symmetry axis ($y \neq \pm 1$), $\Lambda$ vanishes (at the event horizon), whereas for the points on the symmetry axis $y = \pm 1$ at the horizon, $\Lambda$ goes to infinity thereby producing a divergent surface gravity. This particular behavior exhibited in the limit of (47) is the characteristic of the $M$-$Q$ spacetime and has been brought out before in [28].

It should be stressed that this divergence of the surface gravity on the event horizon at $y = \pm 1$, $\Lambda$ is not a ‘directional’ singularity, i.e. surface gravity would diverge at the points $y = \pm 1$, on the horizon, no matter how we approach it, as can be seen from (47). Therefore, such a divergence is not related to a breakdown of the coordinate system as seems to be the case for ‘truly’ directional singularities [39].

Finally, it should be observed that consistency with the third law of thermodynamics would require surface gravity to go to zero when the area goes to zero. This condition is not satisfied for the gamma metric (see discussion in [34]). In our case however the area of the horizon remains finite.

We shall next discuss about the consequences emerging from the results presented so far.

### 6. Conclusions

We have presented a detailed description of the event horizon for the $M$-$Q$ solution. The range of values of $q$ for which that surface is regular, closed, continuous and differentiable has been clearly established.

We have next calculated the area of the event horizon. This quantity plays a central role in the definition of different bounds for black hole entropy (see [38, 40–44] and references therein).

Now, if the gravitational field of the collapsing body, including small deviations from spherical symmetry, is described by means of an exact solution to the Einstein field equations (instead of perturbations of the Schwarzschild spacetime), then it appears that in some particular cases (e.g. the $\gamma$ spacetime) the area surface of the event horizon vanishes leading to the conclusion that as the body falls through the horizon, information about the collapsing body is stripped away, thereby resolving the information loss paradox [23]. However, as we have seen before, this is not the case for the $M$-$Q$ solution; therefore, the conclusion in [23] seems to lack universality and does not apply to any deviation from the spherically symmetric case. Thus, all the discussion about entropy bounds for spherically symmetric black holes
remains basically unchanged for slightly distorted spacetimes (small $q$) in the case of the $M$–$Q$ solution.

On the other hand, however, the result obtained for the surface gravity indicating that it diverges, points in the same direction that the one obtained for the $\gamma$ metric [34] (nevertheless observe that in our case $k$ only diverges on the axis of symmetry, whereas in the $\gamma$ metric case, it diverges everywhere except on the symmetry axis).

Now, the consequences of such divergence might be important and deserve a deeper analysis.

On the one hand, the divergence of $k$ would imply that the ‘inertial’ term in the transport equation would grow unlimited as the horizon is approached.

Indeed, as shown by Tolman many years ago [45], according to special relativity all forms of energy have inertia, and of course this should also apply to heat. Therefore, because of the equivalence principle, there should be also some weight associated with heat, and one should expect that thermal energy tends to displace to regions of lower gravitational potential. This in turn implies that the condition of thermal equilibrium in the presence of a gravitational field must change with respect to its form in the absence of gravity. Thus, a temperature gradient is necessary in thermal equilibrium in order to prevent the flow of heat from regions of higher to lower gravitational potential. This result was confirmed some years later by Eckart [46] and Landau and Lifshitz [47]. In the transport equation derived by these authors, the ‘inertial’ term deduced by Tolman appears explicitly and is essentially the surface gravity multiplied by the temperature. It should be observed that exactly the same term appears also in transport equations derived from, more physically reasonable, causal thermodynamic theories (see [48] for details). In the case of the Eckart and Landau and Lifshitz approach, the transport equation reads

$$q^\alpha = -\kappa h^{\alpha\beta} (T,_{\beta} + T a_{\beta}), \quad (48)$$

where $q^\mu$ is the heat flow four-vector, $V^\mu$ is the four-velocity of a fiducial observer mentioned above, $a^\mu$ is the four-acceleration associated with those fiducial observers, $h^{\mu\nu}$ is the projector onto the three-space orthogonal to $V^\mu$, $\kappa$ denotes the thermal conductivity, and $T$ denotes the temperature.

Therefore the unlimited growing of the ‘inertial’ term as the surface of the object is closer to the event horizon would lead to an increasing inwardly directed heat flow vector, which in turn would produce a substantial increase of temperature. Now, it has been shown (see [48, 49] and references therein) that, as the system leaves the equilibrium, the inertial mass decreases by a factor $(1 - \alpha)$, where $\alpha$ is defined by

$$\alpha = \frac{\kappa T}{\tau (\mu + P_r)}, \quad (49)$$

where $\tau$ is the thermal relaxation time and $\mu$ and $P_r$ denote the energy density and the radial pressure of the fluid, respectively.

Obviously for this effect to be of some relevance in the dynamics of the system, evolution should proceeds in such a way that $\alpha$ approaches the critical value of 1.

Now in cgs units (omitting the pressure term that is always smaller than the energy density), we have

$$\alpha \equiv \frac{\kappa T}{\tau \mu} \approx \frac{1}{81} \frac{[\kappa] [T]}{[\tau] [\mu]} \times 10^{-40}, \quad (50)$$

where $[\kappa]$, $[T]$, $[\tau]$ and $[\mu]$ denote the numerical values of these quantities in erg s$^{-1}$ cm$^{-1}$ K$^{-1}$, K, s and g cm$^{-3}$, respectively.

Thus, in order for $\alpha$ to attain values close to the unity, we need extremely high values of thermal conductivity and/or temperature. In the past [50], it has been suggested that neutrino
Radiative heat conduction might produce values of \( \kappa \) as large as \( 10^{37} \), which together with the expected values of temperature \( T \approx 10^{13} \) at the last stages of massive star evolution, would lead to \( \alpha \approx 1 \).

Here, we see that perturbations of spherical symmetry described by means of the \( M–Q \) spacetime (this also applies to the \( \gamma \) metric case) could provide a mechanism for attaining large values of temperature due to the increase in the heat flow as the source approaches the horizon.

On the other hand, starting from the generalized version of the surface gravity, it appears that its divergence, as we approach the horizon, implies the divergence of the Tolman mass (see [38]). This result, whose dynamical implications cannot be overemphasized, is also obtained for the \( \gamma \) metric (see [51] for a detailed discussion on this point).

Before concluding, the following comment is in order. According to the fact that the black hole has the no-hair theorem, in the process of contraction, all (radiatable) multipole moments are radiated away [52]. Therefore, it could be asked: What the interest might be to study singular horizons as the one corresponding to the \( M–Q \) solution?

Nevertheless, the situation is more complex than it looks at first sight. Indeed, let us admit that in the process of collapse, all (radiatable) multipole moments are radiated away. Obviously, the mechanism of radiation, as any physical process, must act at some time scale (say \( \tau_{\text{mech}} \)). Now, if \( \tau_{\text{mech}} \) is smaller than the time scale for any physical process occurring on the object (say \( \tau_{\text{phys}} \)), then the appearance of a regular horizon proceeds safely.

However, let us suppose for a moment that there is a physical process whose \( \tau_{\text{phys}} \) is of the order of magnitude of (or still worse, smaller than) \( \tau_{\text{mech}} \). In this case, any physical experiment based on such process ‘will see’ a singularity as the boundary of the object crosses the horizon, due to the always present fluctuations.

Indeed, the fact remains that perturbations of spherical symmetry take place all along the evolution of the object. Thus, even if it is true that close to the horizon any of these perturbations is radiated away, it is likewise true that this is a continuous process. Then, as soon as a ‘hair’ is radiated away, a new perturbation appears, which will be later radiated and so on. Therefore, since ‘hairs’ are radiated away at some finite time scale, then at that time scale (\( \tau_{\text{mech}} \)) there will be always a fluctuation acting on the system.

Thus, unless one can prove that indeed \( \tau_{\text{mech}} \) is smaller than \( \tau_{\text{phys}} \), for any physical process, one should take into account the possible consequences derived from the presence of fluctuations of spherical symmetry (close to the horizon); in this later case, such deviations from spherical symmetry might be described (at least in some cases) by the \( M–Q \) spacetime.
