Abstract

 Alternative (unconventional) deep geothermal designs are needed to provide a secure and efficient geothermal energy supply. An in-depth sensitivity analysis was investigated considering a deep borehole closed-loop heat exchanger (DBHE) to overcome the current limitations of deep EGS. A T2Well/EOS1 model previously calibrated on an experimental DBHE in Hawaii was adapted to the current NWG 55-29 well at the Newberry volcano site in Central Oregon. A sensitivity analysis was carried out, including parameters such as: the working fluid mass flow rate, the casing and cement thermal properties and the wellbore radii dimensions. The results conclude the highest energy flow rate to be 1.5MW, after an annulus radii increase and an imposed mass flow rate of 5kg/s. At 3kg/s, the DBHE yielded an energy flow rate a factor of 3.5 lower than the NWG 55-29 conventional design. Despite this loss, the sensitivity analysis allows an assessment of the key thermodynamics within the wellbore and provides a valuable insight into how heat is lost/gained throughout the system. This analysis was performed under the assumption of subcritical conditions, and could aid the development of unconventional designs within future EGS work like the Newberry Deep Drilling Project (NDDP). Requirements for further software development are briefly discussed, which would facilitate the modelling of unconventional geothermal wells in supercritical systems to support EGS projects that could extend to deeper depths.

Keywords: Closed-loop deep borehole heat exchanger; EGS; NDDP; T2Well; EOS1

Introduction

Geothermal energy is an ideal candidate to dominate the energy industry in the foreseeable low-carbon future. Holding a good reputation at providing a constant supply of heat and/or electricity, this mature baseload technology could aid the climate crisis by significantly reducing carbon emissions.

Conventional deep geothermal methods have been utilised to provide power production from natural hydrothermal reservoirs with these desired characteristics: a large heat source, highly permeable, sufficient supply of injected water, impermeable layer of cap rock and a reliable recharge system (DiPippo, 2015). Generally, these sites are unique and restricted by location, severely limiting the true potential of geothermal energy - according to the International Energy Agency, this resource could generate 1400 TWh per year by 2050 while avoiding 800 Mt of CO2 (IEA, 2011). This largely untapped resource demands alternative solutions to compete in
the renewable energy market, specifically exploiting unconventional methods to extract heat, notably from petrothermal sources where permeability and/or porosity are lacking (Falcone et al, 2018). There are significant research gaps for deep unconventional methods where the geothermal gradient is larger than the mean value of 25-30 °C/km (Olasolo et al, 2016). In an Enhanced Geothermal System (EGS), cold water is injected at high pressure into the subsurface to stimulate fractures, hence creating an artificial reservoir (Olasolo et al, 2016). The first EGS project was in Los Alamos (New Mexico), previously defined as a Hot Dry Rock (HDR) project due to lack of natural water saturation in basement rocks (Breede et al, 2013; Olasolo et al, 2016). EGS’s are currently under technical review as they are associated with the risk of inducing seismic activity (Lu, 2018). Examples of abandoned EGS projects due to induced seismicity are the Basel project in Switzerland (Lu, 2018) and the Pohang project in South Korea (Kim et al, 2018). Fundamental research and development on Supercritical EGS (SEGS) is ongoing, such as Iceland’s IDDP projects (Reinsch et al, 2017), the Japan Beyond-Brittle Project (Muraoka et al, 2014) and the DESCRAMBLE project in Italy (Bertani et al, 2018). SEGS’s involve drilling deeper into regions of partial melt past the brittle-ductile transition zone to achieve a larger flow temperature at the bottom of the wellbore (Cladouhos et al, 2018). Here, the fluid is expected to reach a supercritical state, with no clear distinction between the liquid or vapour phase; for pure water, this corresponds to temperature and pressure conditions above approximately T = 374 °C and P = 22.1 MPa (Dobson et al, 2017; Sudarmadi et al, 2012). The development of SEGS’s relies on ultra-high temperature technology, capable of withstanding bottomhole temperatures of 430-550 °C, typical of supercritical environments (Lu, 2018). The IDDP-1 well yielded superheated steam at a temperature of 452 °C and pressure of 140 bar, corresponding to an electricity generation potential of 35 MWe, while in 2017, the IDDP-2 successfully reached supercritical fluids at 426 °C and 340 bar at a depth of 4659 m (DEEPEGS, 2018). However, IDDP-1 drilling was abandoned after hitting a magma intrusion at 900 °C at 2100 m and the first flow test of IDDP-2, conducted in December 2019, encountered delays (DEEPEGS, 2018, 2019). Overcoming the challenges posed by these unique resources could potentially unlock a five times greater energy content and a factor of ten times electricity generation potential associated with supercritical fluids at 400 °C compared with EGS technology at 200 °C (Cladouhos et al, 2018).

Before initiating an in depth numerical investigation of unconventional designs into supercritical geothermal systems, this study presents a foundation for potential usage of this game-changing technology. In this study, an unconventional deep borehole heat-exchanger (DBHE) design is accommodated into the NWG 55-29 open-loop well, to investigate it’s energy performance and potential usage for EGS projects in subcritical environments. It could also aid the development of unconventional designs in supercritical environments when a much greater depth is required - see Borehole settings in Newberry field for details on the current case study investigated.

The conventional BHE design was conceived for shallow depths and low temperature gradients, for heating and cooling applications (Acuña et al, 2011; Beier et al, 2013; Holmberg et al, 2016). Some DBHE sites already exist, including two deep
boreholes in Weissbad and Weggis in Switzerland, at depths of 1.2 km and 2.3 km respectively (Kohl et al, 2000, 2002).

The modelled DBHE involves pumping cold fluid down the outer annulus, such that hot fluid rises to surface up the inner tubing via a thermosiphon effect (natural convection) or through the use of pumps (Tang et al, 2019). The DBHE design was previously modelled in the Villafortuna abandoned oil well in Italy (Alimonti et al, 2016), the KTB deep borehole project setting in Germany (Falcone et al, 2018) and the IDDP-1 well in Iceland (Renaud et al, 2019). Replacing the current NWG 55-29 well with a DBHE would not only mitigate the risks of induced seismicity, but also prevent fluid losses and contamination to the surrounding environment, as the working fluid is not in direct contact with the surrounding rock (Wang et al, 2019). Installation costs can also be reduced by decreasing the boreholes thermal resistance via a thermally enhanced outer pipe in ground-coupled heat pump systems (Raymond et al, 2015). A heat-conducting filler of graphite could also be implemented around the DBHE design to enhance downhole heat transfer (Falcone et al, 2018).

Former DBHE studies have relied upon numerical or analytical methods to discretise the geothermal system into elements within a grid (Alimonti et al, 2018). A research code T2Well/EOS1, recently developed at Lawrence Berkeley National Laboratory for simulating coupled wellbore-reservoir processes involved in geothermal systems, was adopted in this study to model appropriate subcritical conditions in the Newberry volcano area.

**Borehole settings in Newberry field**

This study focuses on the Newberry Volcano EGS project in Central Oregon. This site was one of the first to consider heat extraction from a volcanic source, in addition to developments in hydroshearing stimulation techniques to mitigate induced seismicity and adapting a thermally-degradable zonal isolation material to isolate fractures from intended stimulated zones (Cladouhos et al, 2016). Figure 1 shows the two wellbores locations - NWG 55-29 and NWG 46-16 - along the western flank of the volcano.

From Figure 1, the NWG 55-29 was drilled down to 3067 m with a bottom well temperature of 331 °C (Cladouhos et al, 2016), at subcritical conditions (100 °C < T < 374 °C and 0.1 MPa < P < 22.1 MPa) (Asl and Khajenoori, 2013), and plans to deepen the NWG 46-16 well to 4877 m are in place to transition into supercritical environments (Cladouhos et al, 2018). It is important to note that the wells NWG 55-29 and NWG 46-16 are open-loop designs whereby the pumped working fluid is in direct contact with the reservoir.

A low average flow rate of 3.2 kg/s was obtained from a NWG 55-29 stimulation test, compared to expected conventional EGS flow rates of 50-60 kg/s (Cladouhos et al, 2016; MIT, 2006). As a result of this and of the potential risk of induced seismicity, the DBHE design was chosen for this study. To ensure realistic wellbore properties for the synthetic DBHE in the Newberry settings, casing radii dimensions from existing sites defined previously (Weissbad and Weggis) were applied in this study. See the Sensitivity Analysis section for details.
Methods

The DBHE was modelled into the Newberry geothermal system with a 2D axisymmetric MESH adopting T2Well/EOS1 (Pan and Oldenburg, 2014). The model set-up is described below.

Mathematical Model

T2Well/EOS1 is an integrated wellbore-reservoir numerical simulator to simulate non-isothermal flows of multi-phase fluids (steam-water) in both domains simultaneously (Pruess et al., 2012). T2Well was previously used to model various contexts, such as heat extraction in a closed-loop system with supercritical CO\textsubscript{2} as the working fluid (Higgins et al., 2016) and for a gas storage blow out (Pan et al., 2018). The equation of state (EOS1) was utilised, representing one non-isothermal water component under two-phase conditions (Pruess et al., 2012). The applied thermodynamic equations within the reservoir are similar to those used in other TOUGH2 family code and are defined in Table 1.

Equation (1) depicts the general mass and energy conservation equation with $M^m$, $F^m$, $M^E$ and $F^E$ in Equations (2) to (5) representing the mass accumulation, mass flux, energy accumulation and energy flux terms respectively (Renaud et al., 2020). The phase velocity $u_{ph}$ in Equation (6) is solved by adopting a 3D multi-phase Darcy flow for a heterogeneous porous media.

The key equations for the wellbore used in T2Well/EOS1 are defined in Table 2. Equation (7) depicts the conservation equation in partial derivative form, with $M^E$ defined in Equation (8) and $F^E$ in Equation (9) representing the energy accumulation and flux terms, respectively (Renaud et al., 2020).
Table 1 Key reservoir equations

\[
\frac{d}{dt} \int_{V_n} M^n dV_n = \int_{\Gamma_n} F^n \cdot n d\Gamma_n + \int_{V_n} q^n dV_n \tag{1}
\]

\[M^m = \phi (S_L \rho_L X_L^k + S_G \rho_G X_G^k) \tag{2}\]

\[F^m = X_L^k \rho_L u_L + X_G^k \rho_G u_G \tag{3}\]

\[M^E = (1 - \phi) \rho R T + \phi (\rho L S_L U_L + \rho G S_G U_G) \tag{4}\]

\[F^E = -\lambda \nabla T + h_L \rho_L u_L + h_G \rho_G u_G \tag{5}\]

\[u_{ph} = -\frac{k_a k_r, ph}{\mu_{ph}} (\nabla P_{ph} - \rho_{ph} g) \tag{6}\]

Table 2 Key wellbore equations

\[
\frac{\partial M^n}{\partial t} = q^n + F^n \tag{7}\]

\[M^E = \rho_L S_L (U_L + \frac{u_L^2}{2} + g z \cos \theta) + \rho_G S_G (U_G + \frac{u_G^2}{2} + g z \cos \theta) \tag{8}\]

\[F^E = -\lambda \frac{\partial T}{\partial z} - \frac{1}{\sigma} \frac{\partial}{\partial z} [\sigma \rho_L S_L u_L (h_L + \frac{u_L^2}{2} + g z \cos \theta) + \sigma \rho_G S_G u_G (h_G + \frac{u_G^2}{2} + g z \cos \theta)] \tag{9}\]

The Drift-Flux model (DFM) is used in solving the two-phase momentum conservation equation in the wellbore. A relationship is assumed between the gas velocity \((u_G)\) and the volumetric flux of the mixture \((j)\):

\[u_G = C_0 j + u_d \tag{10}\]

The liquid velocity \(u_L\) can then be calculated from \(j\) and the drift velocity \(u_d\) as:

\[u_L = \frac{1 - S_G C_0}{1 - S_G} j - \frac{S_G}{1 - S_G} u_d \tag{11}\]

The drift velocity is thus calculated as (Pan et al, 2005):

\[u_d = \frac{(1 - C_0 S_G) u_c K(S_G, K_w, C_0) m(\theta)}{C_0 S_G \sqrt{\rho_G / \rho_L + 1 - C_0 S_G}} \tag{12}\]
The velocities \( u_G \) and \( u_L \) within the mixture are then solved with \( u_d \) to obtain the momentum conservation equation; simplified to Equation (13)(Akbar et al, 2016; Pan et al, 2011):

\[
\frac{\partial}{\partial t} (\rho_m u_m) + \frac{1}{\sigma} \frac{\partial}{\partial z} [\sigma (\rho_m u_m^2 + \gamma)] = -\frac{\partial P}{\partial z} - \frac{\Gamma f \rho_m |u_m| u_m}{2\sigma} - \rho_m g \cos \theta \quad (13)
\]

Table 3 defines the remaining parameters from the drift flux model, extracted from Pan and Oldenburg (2014). The mass and energy conservation equations are solved using the Newton Raphson iteration process (Pruess et al, 2012).

### Table 3 Key drift flux parameters in Equation (13)

| Description                              | Equation |
|------------------------------------------|----------|
| Slip between two phases                  | \( \gamma = S_G \rho_G \rho_m [\rho_m^2/(\rho_m^2 - 1)](1 + \gamma)/(1 - S_G) \) |
| Mixture density                          | \( \rho_m = S_G \rho_G + (1 - S_G) \rho_L \) |
| Mixture velocity                         | \( u_m = \frac{[S_G \rho_G u_G + (1 - S_G) \rho_L u_L]}{\rho_m} \) |
| Adjusted average density of mixture      | \( \rho_m^* = S_G C_0 \rho_G + (1 - S_G C_0) \rho_L \) |

**Newberry case study**

The DBHE was modelled into the Newberry geothermal system by replacing the NWG 55-29 well with the unconventional closed-loop design. The DBHE model built with T2Well/EOS1 is based on an experimental study from Morita et al (1992b), whereby the measured and computed pressure and temperature values were verified with the HGP-A well site in Hawaii (Morita et al, 1992b). The original completion diagram from Morita et al (1992b) was altered to account for the increase in depth from 879.5 m to the NWG 55-29 wellbore depth of 3067 m (Cladouhos et al, 2016).

A 2D axisymmetric grid representation of the design is presented in Figure 2 below; note Casg1(A.) is the inner casing separating the outer annulus and the inner tubing and Casg2(B.) is the external casing separating the outer annulus and the cement, Ceme1(D.). Figure 2 highlights key elevation depths for each section to account for these changes. The bottom of the well reached an elevation of -1267 m.

The Newberry geothermal area was defined according to the thermal-hydrological-chemical model adopted from Sonnenthal et al (2012). Four geological zones are highlighted in Figure 2 below with their thermodynamic properties in Table 4, obtained from (Sammel et al, 1988; Sonnenthal et al, 2012). Thermodynamic wellbore properties are also defined in Table 5 below, incorporated from Falcone et al (2018); Morita et al (1992a).

Referring to Figure 2, water was injected into the outer annulus at a temperature of 12 °C with an imposed mass flow rate \( \dot{m} \). The top boundary condition of the reservoir model was set with a surface temperature of 12 °C and a surface atmospheric pressure of 1 bar (Sonnenthal et al, 2012). As shown in Sonnenthal et al (2012), it was assumed in the model that the surface pressure and temperature values were constant at elevation +1600 m, neglecting the pressure and thermal losses in the water table defined between +1800 m and +1600 m. The default pressure for the boundary condition on the DBHE was set to 3 bar (as shown by \( P_i \)) to prevent effects from local vacuum conditions reaching the lower limit of the code. Only heat flow was considered between the wellbore and reservoir to reflect the closed-loop design, excluding fluid flow.
Figure 2 Geological Setting and Well Completion Diagram of DBHE design implemented in T2Well/EOS1. Left - Geological Setup, with four key zones at defined depths in the z axis (+1599.50 m to –1580 m). Numbered labels are supported by thermodynamic properties in Table 4 below. Right - 2D asymmetric scheme containing 2752 cells in the r (1 – 200 m) and z axis, interpreted from Morita et al (1992b); Sonnenthal et al (2012). Well completion diagram of the DBHE interpreted from Cladouhos et al (2016). Both depict the casing and cement sections at appropriate elevations in T2Well/EOS1, interpreted from (Tang et al, 2019; Toth, 2015).

Table 4 Key Geological Settings in support of Figure 2 (left) above

| Key | Geological Name          | Altitude Range | Thermodynamic Properties |
|-----|--------------------------|----------------|--------------------------|
| 1.  | Newberry – Deschutes (upper) | +16000m to +1400m | \( \rho = 2700 \text{ kg/m}^3 \) \( c_P = 1000 \text{ J/kg/}^\circ\text{C} \) \( \Phi = 0.2 \text{ (20\%)} \) \( K = 0.15 \times 10^{-11} \text{ m}^2/\text{K} \) \( \lambda = 1.7 \text{ W/mK} \) |
| 2.  | Newberry - Deschutes | +1400m to +300m | \( \Phi = 0.1 \text{ (10\%)} \) \( K = 0.1 \times 10^{-16} \text{ m}^2/\text{K} \) \( \lambda = 1.8 \text{ W/mK} \) |
| 3.  | John Day | +300m to - 800m | \( \Phi = 0.05 \text{ (5\%)} \) \( K = 2.6 \times 10^{-16} \text{ m}^2/\text{K} \) \( \lambda = 2.15 \text{ W/mK} \) |
| 4.  | Intruded John Day | -800m to -1500m | \( \Phi = 0.03 \text{ (3\%)} \) \( K = 0.5 \times 10^{-17} \text{ m}^2/\text{K} \) \( \lambda = 2.15 \text{ W/mK} \) |

1 All properties apart from \( \rho \) and \( c_P \) are cited from Sonnenthal et al (2012).
2 All rock properties have identical \( \rho \) and \( c_P \) variables, quoted from Sammel et al (1988).

Table 5 Key Borehole properties in support of Figure 2 (right) above.

| Key | Borehole Section | Name of Section | Thermodynamic Properties |
|-----|-----------------|-----------------|--------------------------|
| A.  | Insulated inner pipe | Casg1 | \( \rho = 2700 \text{ kg/m}^3 \) \( c_P = 470 \text{ J/kg/}^\circ\text{C} \) \( \Phi = 0 \text{ (0\%)} \) \( K = 0 \text{ m}^2/\text{K} \) \( \lambda = 0.01038 \text{ W/mK} \) |
| B./C. | Casing | Casg2/Casg3 | \( \rho = 2700 \text{ kg/m}^3 \) \( c_P = 470 \text{ J/kg/}^\circ\text{C} \) \( \Phi = 0.1 \text{ (10\%)} \) \( K = 0 \text{ m}^2/\text{K} \) \( \lambda = 46.1 \text{ W/mK} \) |
| D./E. | Cement | Ceme1/Ceme2 | \( \rho = 1830 \text{ kg/m}^3 \) \( c_P = 1900 \text{ J/kg/}^\circ\text{C} \) \( \Phi = 0.1 \text{ (10\%)} \) \( K = 0 \text{ m}^2/\text{K} \) \( \lambda = 0.99 \text{ W/mK} \) |

1 Insulated inner casing, sourced from Falcone et al (2018). Other parameters sourced from Morita et al (1992a).
T2Well numerical validation

Experimental validation

The experimental data from a DBHE in Hawaii set at the depth of 879.6 m was used to validate the T2Well model (Morita et al, 1992b). The pressure and temperature distribution in the first 12 hours showed a good match between measured values and simulations as illustrated in Figure 3. Model properties and details can be found in Renaud et al (2020).

Figure 3 Left - Transient pressure simulation with T2Well compared to measurements from Morita et al (1992b). Right - Transient temperature simulation with T2Well compared to measurements from Morita et al (1992b)

Numerical discussion

A DBHE with graphite on the wellbore was numerically investigated using FE-FLOW (Falcone et al, 2018). While authors in Falcone et al (2018) used constant water properties, T2Well uses the pressure and temperature dependent thermophysical properties based on models suggested by the International Formulation Committee (IFC, 1967). As stated in Sui et al (2019); Tang et al (2019), constant fluid properties seem to generate errors in the pressure losses calculation and heat produced in DBHEs. The produced water temperature and heat flux were underestimated for a DBHE of 6100 m (Alimonti and Soldo, 2016) and overestimated by 11% in a DBHE of 3500 m (Hu et al, 2020). These errors occurred due to not accounting for specific heat capacity and density changes within the DBHE. Compared with constant water properties, these changes would increase the total heat energy while decreasing the temperature of the return fluid.

The same deep geothermal system was modeled based on the KTB deep borehole project, reaching a reservoir depth of 8000 m (Falcone et al, 2018), using T2Well/EOS1. While a 3D model was considered in Falcone et al (2018), the T2Well model used in this work is an axisymmetric RZ mesh centred on the wellbore. Graphite is implemented with a thermal conductivity value of 300 W/m.K and an assumed porosity of 1%.

The T2Well grid contains 1030 elements. The maximum radial extension of the model is 1 km. The bottom of the DBHE was set at a depth of 7000 m. Water was
injected in the annulus at the flow rate of 304.8 m$^3$/d ($\sim$ 7 kg/s). The reservoir was assumed to be fully saturated water. The surface temperature was set to 15 °C, with an initial temperature gradient of 40 °C/km. The bottom temperature is 330 °C. The graphite filled the surrounding of the DBHE from the depth of 4400 and 7200 m instead of the cement or grout. The value of casing materials is 900 J/kg.K and the wall roughness is $2.5 \times 10^{-5}$ m. The thermal properties of the rock and DBHE sections applied in the model can be found in Falcone et al (2018); Seyidov (2016). Fig. 4 describes the water temperature at the surface of the DBHE compared to the FEFLOW results.

![Figure 4](image.png)

**Figure 4** Numerical results comparison from Falcone et al (2018) and the T2well/EOS1 model.

From this case study, the temperature obtained at the surface of the DBHE was lower than previously described in Falcone et al (2018), suggesting the potential overestimation of the water temperature using constant water properties due to changes in the specific heat value (Song et al, 2018). As stated by Hu et al (2020), the temperature dependent properties as calculated in T2Well/EOS1, must be considered for long term performance evaluation of DBHE.

**Sensitivity Analysis**

Table 6 summarises the parameters investigated in this study: mass flow rate of water $\dot{m}$ (kg/s), thermal conductivity $\lambda$ (W/mK) of the casings and cement (see Figure 2), and the wellbore inner $r_i$ (m) and outer $r_o$ (m) radii dimensions for the annulus and tubing. All parameter changes were referenced against a base case scenario from Morita et al (1992b).

The working fluid velocity $u_F$ at the bottom of the well was explored for values 3 kg/s < $\dot{m}$ < 9 kg/s (See Mass Flow rate section).

An insulated inner casing is advantageous for preventing heat losses between the inner tubing and the outer annulus, hence maximising the extracted energy flow rate at the outlet (Falcone et al, 2018; Song et al, 2018). Therefore, the effectiveness of an insulated inner casing as inner tubing for the DBHE was investigated by adjusting $\lambda$ (W/m.K) of Casg1 whilst $\dot{m}$ was fixed at 5 kg/s. Note 46.1 W/m.K was chosen as an upper limit to explore the heat transfer through the design when all three casing
properties are identical - Casg2 = Casg3 at $\lambda = 46.1$ W/m·K - (see Inner casing properties section).

Fixing Casg1 at $\lambda = 0.01038$ W/m·K and $\dot{m} = 5$ kg/s, the outer casing thermal conductivity $\lambda$ was adjusted based on quoted values in Table 6. The casing properties extracted from the Weissbad DBHE and the NWG 55-29 well were explored here (see Outer casing properties section).

Fixing $\dot{m}$, Casg1 and Casg2 properties to the base case values quoted in Table 6, the thermal conductivity $\lambda$ parameter for various cements was explored. The use of a heat conducting filler for enhanced heat transfer (graphite flakes positioned laterally and parallel to one another) was also investigated (Falcone et al, 2018) at $\lambda = 300$ W/m·K (see Cement properties section).

### Table 6 Parameter changes investigated in the DBHE model.

| Parameters       | Values | Description | Base case |
|------------------|--------|-------------|-----------|
| $\dot{m}$ (kg/s) | 3-5-7-9|             | 5         |
| Inner casing properties |
| Casg1 $\lambda$ (W/mK) | 0.01038 | Insulated 1 |           |
|                   | 1.163  | Morita 2    |           |
|                   | 2.5    |             |           |
|                   | 46.1   | Morita 3    | 0.01038   |
| Outer casing properties |
| Casg2-3 $\lambda$ (W/mK) | 46.1   | Morita 7    |           |
|                   | 45.0   | Weissbad 4  |           |
|                   | 15.0   | Newberry 5  | 46.1      |
|                   | 0.01038| Insulated 1 |           |
| Cement properties |
| Ceme 1-2 $\lambda$ (W/mK) | 0.99   | Morita 4    |           |
|                   | 2.24   | REF concrete 6 |       |
|                   | 3.52   | GRAP concrete 6 | 0.99 |
|                   | 300    | Graphite flakes 1 |     |
| Radii |
| Annulus radii $r_i/r_o$ (m) | 0.0797/0.0889 | Morita |           |
|                   | 0.0629/0.0721 | Case 1 |           |

1 Insulated inner casing 0.01038 W/mK, cited from Falcone et al (2018).
2 Thermal conductivity values quoted from Morita et al (1985).
3 Thermal conductivity values quoted from Morita et al (1992a).
4 Weissbad parameters quoted from Kohl et al (2000).
5 Newberry parameters quoted from Cladouhos (2012).
6 Cement parameters obtained from Asadi et al (2018).

Four wellbore radii cases were investigated: annulus reduction (Case 1), annulus increase (Case 2), tubing increase (Case 3) and tubing reduction (Case 4) against the base case radii dimensions from Morita et al (1992b). Again, the mass flow rate was fixed at $\dot{m} = 5$ kg/s. Case 1 involved an annulus reduction by 1.27, incorporating $r_i = 0.0629$ m from the Weggis plant (Kohl et al, 2002). Case 2 involved an annulus increase by 1.33 by implementing $r_i = 0.1061$ m from the Weissbad well (Kohl et al, 2000). Case 3 values were chosen so the tubing increase factor was equal to that of Case 2 (1.33). Case 4 tubing reduction by 1.22 was influenced by $r_o = 0.0365$
m tubing dimension from the Weggis well (Kohl et al, 2002). For all radii changes, the annular space between \( r_i \) and \( r_o \) remained constant at 0.0092 m and 0.0192 m for the annulus and tubing respectively. The cross sectional area ratio between the annulus and tubing was also explored, by adopting equations (14) and (15) respectively below:

\[
\sigma_A = \pi (r_{i,A}^2 - r_{o,T}^2) \tag{14}
\]

\[
\sigma_T = \pi r_{i,T}^2 \tag{15}
\]

Where \( r_{i,A} \) is the inner annulus radii, \( r_{o,T} \) is the outer tubing radii and \( r_{i,T} \) is the inner tubing radii. See Radii section for more details.

The heat transfer down the outer annulus and up the inner tubing was investigated for each parameter change and compared to the base case scenario from Morita et al (1992b) seen in Table 6. For each parameter change, the temperature \( T(\degree C) \) and pressure \( P(MPa) \) vs elevation (m) was investigated over a total simulation time of 30 years. In addition, the simulated energy flow rate of the wellbore \( q_{Th}(MW) \) was also extracted from the output file. A review on the energy flow rate for the closed-loop DBHE vs open-loop NWG 55-29 wellbore was explored and concludes this study. The energy flow rate is estimated for the NWG 55-29 wellbore by adopting equation (16) below:

\[
q_{Th} = c_P \dot{m} \Delta T \tag{16}
\]

Where \( \Delta T = T_o - T_i \), \( T_o = 94 \degree C \) representing the first flow back temperature recorded at the outlet point of the NWG 55-29 wellbore (Cladouhos et al, 2016) and \( T_i = 12 \degree C \) is the surface temperature of the Newberry environment (Sonnenthal et al, 2012). \( c_P = 4200 \text{ J/kg}\degree C \) is assumed a constant for pure water properties. See Energy flow rate comparison between DBHE and NWG 55-29 section for details.

**Results**

**Mass flow rate**

Figure 5 shows the temperature and pressure distributions along the DBHE for varied \( \dot{m} \). Table 7 highlights key thermodynamic properties from Figure 5 and the simulation output file: \( \Delta T \) between inlet \( T_i \) and outlet \( T_o \) points, energy flow rate \( q_{Th} \) and the working fluid velocity \( u_F \) at the bottom of the wellbore:

From Figure 5, it appears that an increase in \( \dot{m} \) results in a lower bottom well temperature (32 \degree C for 9 kg/s in comparison to 73 \degree C for 3 kg/s). This decrease is observed in response to an increase in working fluid velocity (4.42 m/s vs 1.51 m/s), leading to a shorter residence time. An increased \( \dot{m} \) up the tubing results in a lower outlet temperature (34.5 \degree C for 9 kg/s in comparison to 71.4 \degree C for 3 kg/s).

A slight gain in temperature up the tubing is also observed (a 2.48 \degree C increase for 9 kg/s in comparison to a 2.06 \degree C decrease for 3 kg/s). This could be due to a
higher pressure reduction up the tubing ($\Delta P = 43.7$ MPa for 9 kg/s vs $\Delta P = 29.4$ MPa for 3 kg/s).

A mass flow rate value of 9 kg/s displays the highest $q_{Th}$ compared with 3 kg/s and yields the largest $\Delta T$ up the tubing. Ideally, $\Delta T$ should be minimised up the tubing to enhance the systems efficiency by extracting more heat from the surrounding formations. A balance between efficiency and energy flow rate should be achieved. Due to 9 kg/s causing too high of a friction loss up the tubing and inducing higher pumping costs as shown by an increased inlet pressure (15.9 MPa as opposed to 1.62 MPa for 3 kg/s), and 3 kg/s yielding the lowest energy flow rate (1.14 MW), 5 kg/s is considered the best-case scenario with minimal $\Delta T$ up the tubing and an energy flow rate of $q_{Th} = 1.46$ MW.

**Inner casing properties**

Figure 6 shows the temperature and pressure distributions along the DBHE for varied $\lambda$ in Casg1. Table 8 summarises key thermodynamic properties extracted from Figure 6 and from the simulation output file: $\Delta T$ between inlet ($T_i$) and outlet ($T_o$) points and the energy flow rate $q_{Th}$.

$\Delta T$ down the annulus is seen to increase while $\lambda$ increases in Casg1 ($\Delta T = 39.2$ °C for $\lambda = 0.01038$ W/m.K compared with $\Delta T = 216$ °C for $\lambda = 46.1$ W/m.K). This is in agreement with Fourier’s law of heat conduction (Nuclear-power.net, 2019) via an increase in heat transfer from the reservoir into the wellbore. The inlet pressure remains approximately constant at 5 MPa due to the constant mass flow rate of 5 kg/s imposed. In addition, the outlet pressure remains constant at 0.3 MPa.
Using a thermal conductivity $\lambda > 0.01038 \text{ W/m.K}$, the temperature up the tubing significantly reduces as a result of low thermal insulation between the annulus and tubing (Song et al, 2018). For maximum efficiency, $\Delta T$ should be minimised to follow an isothermal process to surface. In fact, $\lambda = 46.1 \text{ W/mK}$ is considered the worst-case scenario when all casing properties are identical and thermal insulation is at its lowest.

![Figure 6](image)

**Figure 6** Thermal conductivity analysis in inner casing (Casing 1) over 30 years Left - Temperature vs Elevation for various $\lambda(W/mK)$. Right - Pressure vs Elevation for various $\lambda(W/mK)$. Solid lines represent annulus and dashed lines tubing data respectively. Legend applies to both graphs. All cases were compared to the base-case graph (in blue).

Table 8 Key thermodynamic properties for various $\lambda(W/mK)$ quoted to 3.s.f

| $\lambda(W/mK)$ | $\Delta T(\degree C)$ | $q_{Th}(MW)$ |
|-----------------|------------------------|--------------|
| 0.01038         | 38.9                   | 1.46         |
| 1.163           | 33.3                   | 1.35         |
| 2.5             | 28.8                   | 1.25         |
| 46.1            | 8.19                   | 0.830        |

A higher $\lambda$ yields a smaller $\Delta T$ between the inlet and outlet points and hence a smaller energy flow rate $q_{Th}$ (0.830 MW vs 1.46 MW), again due to poor thermal insulation. Therefore, minimising the thermal conductivity in Casing 1 ($\lambda = 0.01038 \text{ W/mK}$) is the best-case scenario to achieve maximal bottomhole $T$ and preventing significant cooling of the fluid up the tubing.

**Outer casing properties**

Figure 7 displays the temperature and pressure distributions along the DBHE for varied $\lambda$ in the outer casing. The first three parameter changes result in nearly identical temperature and pressure profiles. Therefore, two cases were compared: $\lambda = 0.01038 \text{ W/m.K}$ for the inner Casing 1 only (red), and for all casings (green). Table 9 highlights key thermodynamic properties from Figure 6 and the output file: $\Delta T$ between inlet $T_i$ and outlet $T_o$ points, the inlet $P_i$ and outlet $P_o$ pressure points and the simulated energy flow rate $q_{Th}$ for these two cases.

When all casings are insulated at $\lambda = 0.01038 \text{ W/m.K}$, a lower bottomhole temperature (17.2 $\degree C$ vs 50.4 $\degree C$) is observed in addition to a lower outlet temperature.
Figure 7 Thermal conductivity analysis in outer casings for fixed $\dot{m} = 5\,(kg/s)$ over 30 years. Left - Temperature vs Elevation for various $\lambda\,(W/mK)$. Right - Pressure vs Elevation for various $\lambda\,(W/mK)$. Solid lines represent annulus and dashed lines tubing data respectively. The base-case graph here is highlighted in red.

Table 9 Key results comparing insulating properties for only Casg1 and for all casings to 3.s.f

| Key Results | Only Casg1 | All Casings |
|-------------|------------|-------------|
| $T_i$\,(°C) | 11.1       | 10.9        |
| $T_o$\,(°C) | 50.0       | 17.8        |
| $\Delta T$\,(°C) | 38.9       | 6.92       |
| $P_i$\,(MPa) | 4.97       | 5.23        |
| $P_o$\,(MPa) | 0.302      | 0.302       |
| $q_{Th}$\,(MW) | 1.46       | 0.785      |

($T_o = 17.8\,^\circ C$ vs $T_o = 50.0\,^\circ C$). This is due to insufficient heat transfer between the reservoir and wellbore. $\Delta T$ between the inlet and outlet points decreases approximately by a factor of 6 ($6.92\,^\circ C$ vs $38.9\,^\circ C$) and hence results in a reduction in $q_{Th}$ (0.785 MW vs 1.46 MW) as the water fails to gain significant temperature down the annulus when all casings are insulated. Therefore, to ensure an efficient thermal recovery, the best-case scenario is observed when only the inner casing is insulated at $\lambda = 0.1038\,W/mK$ compared to all casing. This is because Casg1 is most sensitive to $\Delta T$ up the tubing - as seen in Mass flow rate section above.

Cement properties

Figure 8 shows the temperature and pressure distributions along the DBHE for varied $\lambda$ cement properties (Ceme1 and Ceme2 in Figure 2). Key thermodynamic properties extracted from Figure 8 and from the simulation output file are summarised in Table 10: $\Delta T$ between inlet $T_i$ and outlet $T_o$ points, and the simulated energy flow rate $q_{Th}$.

The bottomhole temperature down the annulus increases from $50.4\,^\circ C$ to $60.9\,^\circ C$ for $\lambda = 0.99\,W/m.K$ and $\lambda = 300\,W/m.K$ respectively. Hence, $T_o$ increases as a result of an increase in $\lambda$ within the cement, suggesting this parameter change enhances the amount of heat transfer between the reservoir and working fluid. In particular, this heat transfer is hindered when $\lambda$ is lower than that of the reservoir, as identified in Song et al (2018). As $\lambda$ predominantly affects $T$ and not $P$ (as seen
in Inner tubing properties section), the pressure distribution along the DBHE shows similar results for all parameter changes. Referring to Table 10, \( \lambda \) is maximised in conjunction with \( q_{Th} \), with a percentage increase of 14.4% comparing conventional cement with a graphite heat conductive filler (1.67 MW for \( \lambda = 0.99 \text{ W/m.K} \) vs 1.46 MW for \( \lambda = 300 \text{ W/m.K} \)). While the use of graphite significantly empowers the heat transfer in the DBHE design, its use as a cement additive is an unproved concept. Therefore, \( \lambda < 3.52 \text{ W/m.K} \) parameters are deemed more reasonable as best-case scenario’s because conventional cement falls into the region of \( 0.2 < \lambda < 3.63 \text{ W/m.K} \) (Ichim et al, 2016).

![Figure 8 Thermal conductivity analysis in cement layers for fixed \( \dot{m} = 5(kg/s) \) over 30 years. Left - Temperature vs Elevation for various \( \lambda(W/m.K) \). Right - Pressure vs Elevation for various \( \lambda(W/m.K) \). Solid lines represent annulus and dashed lines tubing data respectively. Legend applies to both graphs. The base-case graph here is highlighted in blue.](image)

**Table 10 Key thermodynamic properties for various \( \lambda (W/m.K) \) to 3.s.f**

| \( \lambda (W/mK) \) | \( \Delta T (^\circ C) \) | \( q_{Th} (MW) \) |
|----------------------|-----------------|-----------------|
| 0.99                 | 38.9            | 1.46            |
| 2.24                 | 43.8            | 1.57            |
| 3.52                 | 45.5            | 1.60            |
| 300                  | 49.0            | 1.67            |

Radii

Figure 9 shows the temperature and pressure distributions along the DBHE for varied radii. Two key scenarios were analysed: varying the inner annulus radius (Case1 and Case2) and increasing the tubing radii by a factor of 1.33 (Case3). Each scenario was then compared to the original base-case radii from Morita et al (1992b), with a constant mass flow rate \( \dot{m} = 5 \text{ kg/s} \). Table 11 highlights the key thermodynamic properties from Figure 9 and the output file for each scenario respectively: \( \Delta T \) between inlet \( T_i \) and outlet \( T_o \) points, the inlet \( P_i \) and outlet \( P_o \) pressure points, the simulated energy flow rate \( q_{Th} \) and the working fluid velocity \( u_F \) at the bottom of the well. The cross sectional area values for the annulus \( (\sigma_A) \) and tubing \( (\sigma_T) \) are also quoted along with their ratio \( (\sigma_A/\sigma_T) \).
Concerning the annulus comparison in Table 11, the bottomhole temperature decreases from 50.4 °C to 48.8 °C alongside an inner radius reduction (Case1) and increases to 52.3 °C alongside an inner radius increase (Case2). This occurs due to variation in the annulus cross sectional area (0.0291 m² vs 0.00621 m²). For Case2, the annulus cross sectional area decreases the working fluid velocity down the annulus. This leads to a longer residence time and hence enhanced heat transfer within the wellbore, as discussed in Nalla et al (2005). $T_o$ also shows this trend, decreasing from 50.0 °C to 48.5 °C for Case1 and increasing to 51.8 °C for Case2.

Table 11 Key results when varying annulus with original radii dimensions to 3.s.f

| Key Results | Original | Case1 | Case2 | Case3 |
|-------------|----------|-------|-------|-------|
| $T_i$ (°C)  | 11.1     | 10.9  | 11.2  | 11.8  |
| $T_o$ (°C)  | 50.0     | 48.5  | 51.8  | 49.6  |
| $\Delta T$ (°C) | 38.9 | 37.6  | 40.6  | 37.8  |
| $P_i$ (MPa) | 4.97     | 5.90  | 4.87  | 1.35  |
| $P_o$ (MPa) | 0.302    | 0.302 | 0.302 | 0.300 |
| $u_F$ (m/s) | 2.48     | 2.48  | 2.48  | 1.41  |
| $q_{Th}$ (MW) | 1.46 | 1.43  | 1.50  | 1.45  |
| $\sigma_A$ (m²) | 0.0137 | 0.00621 | 0.0291 | 0.0112 |
| $\sigma_T$ (m²) | 0.00201 | 0.00201 | 0.00201 | 0.00354 |
| $\sigma_A/\sigma_T$ | 6.83 | 3.09 | 14.5 | 3.16 |

$P_i$ is seen to slightly increase from 4.97 MPa to 5.90 MPa for an inner annulus radius reduction (Case1) and decrease from 4.97 MPa to 4.87 MPa for an inner annulus radius increase (Case2) due to changes in the cross sectional area ratio (3.09 vs 14.5). Therefore, in order to impose a constant $\dot{m}$, the return pressure will decrease as a result of this increased cross sectional area ratio for Case2. Both Case1 and Case2 reach an equal bottomhole pressure of 33.1 MPa which results in $P_o \approx 0.302$ MPa for both cases. This occurs due to the constant cross sectional area witnessed in the tubing (0.00201 m²).

$q_{Th}$ increased from 1.46 MW to 1.50 MW alongside an inner annulus radius increase (Case2) and slightly decreased to 1.45 MW for an inner annulus radius reduc-
Figure 10 Illustration for Cases 1 and 2 at the bottom of the well. Working fluid velocity $u_F$ and frictional pressure $F$ values are shown for Cases 1 and 2. These values were extracted from the output files for connections between the bottom cell and the one above, as depicted by the red vertical arrows. The horizontal arrow is not modelled in T2Well/EOS1 but is here to represent the differences between the two cells. This image is not to scale.

...tion (Case1). The former is influenced by an increase in the working fluid velocity and cross sectional area as discussed previously. In addition, there is a decrease in frictional pressure down the annulus (254 Pa/m vs 3.04 Pa/m in Figure 10), and hence an increased heat transfer and increased $\Delta T$ between the inlet and outlet points. Therefore, a radii increase in the annulus (Case2) is the best-case scenario here for maximal energy flow rate.

Case4 (tubing reduction by 1.22) failed to run for $\dot{m} = 5$ kg/s due to a change in pressure into the wellbore that exceeded the limits of the software, 1000 bars (Renaud et al, 2018). For a constant $\dot{m} = 5$ kg/s, at time $t = 0$, the pressure seen at the bottom of the well was $0.25 \times 10^8$ Pa but below the DBHE in the surrounding formation the pressure reached $1 \times 10^9$ Pa, i.e. 1000 bars. Therefore, a detailed comparison between Case3 and Case4 could not be achieved. Instead, an inner tubing radius increase (Case3) was compared with respect to the original radii - referring to Figure 9 and Table 11.

A slight increase in temperature down the annulus from $50.4 \, ^\circ C$ to $50.9 \, ^\circ C$ is seen for an inner tubing radius increase (Case3). This occurs due to a decreased upward velocity in the tubing (1.41 m/s vs 2.48 m/s), leading to enhanced heat loss from the tubing into the annulus – see Figure 11. In addition, the outer temperature has slightly decreased ($49.6 \, ^\circ C$ vs $50.0 \, ^\circ C$) when the cross-sectional area in the tubing increased. Down the annulus however, the working fluid velocity has increased (0.446 m/s vs 0.363 m/s), in addition to an increase in frictional pressure (50.6 Pa/m vs 23.7 Pa/m).

In order to maintain the imposed mass flow rate $\dot{m} = 5$ kg/s at the inlet point, the inlet pressure for Case3 has decreased ($P_i = 1.35$ MPa vs 4.87 MPa) following an increase in the working fluid velocity at the inlet point described above. In addition, the increased frictional pressure down the annulus (50.6 Pa/m vs 23.7 Pa/m) consequently slows down the working fluid velocity in the tubing (1.41 m/s vs 2.48 m/s) and a reduced inlet pressure is witnessed. Despite this ratio yielding a factor of 2 lower than that of the original radii (3.16 vs 6.83), this loss in $P_i$ is due to a slight reduction in the annulus cross sectional area (0.0112 m$^2$ vs 0.0137 m$^2$) and the reduced working fluid velocity witnessed in the tubing.
It is seen to be nearly identical at 1.46 MW for Case3 and the original radii. It can be inferred that when the inner tubing radius increases, there is little influence on the value of $q_{Th}$ apart from a slight heat loss up the tubing. On the contrary, adjusting the tubing will affect the inlet pressure and hence the costs associated with the imposed energy flow rate. To avoid high energy consumption associated with a high injection pressure, a tubing reduction (Case3) could be considered a viable option for future designs to sustain a good energy flow rate.

In comparison, adjusting the annulus radii heavily influences the extent of heat transfer down the annulus. For an increased annulus radius, the heat transfer down the annulus increases and offers a higher $q_{Th}$ from an increased bottomhole temperature. The best-case scenario concluded here is for a radius increase in the annulus (Case2) to increase the energy efficiency of the system. However, according to Nalla et al (2005), adjusting the radii can incur high drilling costs - from the analysis a tubing reduction (Case3) could be suggested as an alternative.

It is worth noting that the assumption of a constant wellbore radius along the wellbore is only a preliminary step, as wells are conventionally drilled with decreasing diameter sections at increasing depths (Nalla et al, 2005). However, keeping a constant radius for the entirety of the wellbore depth simplifies the model, as experimented in Morita et al (1992b).

**Energy flow rate comparison between DBHE and NWG 55-29**

Assuming an average flow rate of 3.2 kg/s, and $\Delta T = 94 - 12 = 82 \, ^{\circ}C$ obtained from the first NWG 55-29 flow back test (Cladouhos et al, 2016), in addition to $c_P = 4200 \, J/kg^{\circ}C$ for pure water, the energy flow rate obtained at the wellhead of NWG 55-29 is approximately $q_{Th} = 1.10 \, MW$. Comparing this to the DBHE results at 3 kg/s - $q_{Th} = 1.14 \, MW$ - it can be inferred that the DBHE offers a slightly higher energy flow rate at the wellhead compared to the NWG 55-29 open-loop well with a percentage increase of 3.44%. It is important to note that this comparison is an estimate and in reality, $\dot{m}$ and $c_P$ will vary considerably with depth.

A comparison between the two designs is also interpreted by assessing the bottomhole temperature at a fixed depth of 3067 m. Assuming no major temperature
losses up the tubing ($\pm 5 \, ^{\circ}C$), the temperature at the wellbore bottom can be regarded as the temperature at the outlet point.

The highest bottomhole temperature observed in this sensitivity analysis without significant heat loss up the tubing is 73.4 $^{\circ}C$ for 3 kg/s in the $m$ parameter change, whereas the conventional open-loop NWG 55-29 wellbore reached a static bottomhole temperature of 331 $^{\circ}C$ (Cladouhos et al, 2016). Both examples are at a fixed depth of 3067 m. Taking $\Delta q_{Th} = 0.956 - (-0.200) = 1.16$ MW as the simulated energy flow rate between the wellbore bottom and the inlet point for 3 kg/s, a comparison can be made with that obtained in the conventional NWG 55-29 well.

Assuming constant parameters $m = 3$ kg/s, $c_P = 4200 \, J/kg^{\circ}C$ for pure water and $\Delta T = 331 - 12 = 319 \, ^{\circ}C$, then $q_{Th} = 4.02$ MW for the NWG 55-29 wellbore in comparison to $q_{Th} = 1.16$ MW for the DBHE design. This concludes that the closed-loop DBHE design offers an energy flow rate output approximately a factor of 3.5 lower than that of the conventional design.

However, the highest energy flow rate obtained in the $m$ analysis was for 9 kg/s - yielding $\Delta q_{Th} = 1.45 - (-0.614) = 2.06$ MW for a bottomhole temperature of 32.1 $^{\circ}C$ in comparison to $q_{Th} = 12.1$ MW for the NWG 55-29 wellbore at a fixed $m = 9$ kg/s. This yields an energy flow rate drop for the DBHE of approximately a factor of 5.84 lower in comparison to the static NWG 55-29 bottomhole temperature of 331 $^{\circ}C$.

These mass flow rates were chosen for comparison because according to Cladouhos et al (2016), similar values were obtained for an initial flow test (9.5 kg/s down to 5.7 kg/s after 1 hour, with an average flow rate 3.2 kg/s).

The estimate of $q_{Th}$ for NWG 55-29 carries some uncertainty, especially when defining $c_P$ because phase changes will occur with depth and the specific heat capacity will change. In the T2Well/EOS1 software, these phase changes are taken into account so the simulated energy flow rate values will carry accuracy. Nevertheless, it can be inferred that the closed-loop design is associated with a lower heat extraction potential compared to that of an operating EGS (assuming the EGS is successful) – especially when the closed-loop design offers lower wellhead temperatures, according to Alimonti et al (2018). However, a DBHE solution for the current NWG 55-29 well would not require stimulation to create an artificial reservoir, and hence less energy consumption is initially used up. This energy consumption for the current NWG 55-29 could outweigh the lower heat extraction potential seen from the DBHE design, hence bringing forward potential benefits for accommodating the DBHE design in this setting from this numerical study. Furthermore, the DBHE is a closed system, which enables easy monitoring and prevents fluid losses and pipe corrosion/blockage. For EGS projects where unexpected failures occur, the DBHE design could be an effective alternative. For example, an EGS site at Rosemanowes in Cornwall failed to create artificial fractures and suffered fluid loss of 70% - leading to project abandonment in 1991 (Lu, 2018). EGS activities in Cornwall, UK is ongoing and having the DBHE as a backup option could be beneficial, especially if drilling does not meet expectations.

While supercritical depths in the Newberry reservoir could not be modelled in this study due to software limitations, numerical wellbore-reservoir modelling will
need to be further developed by adopting a supercritical equation of state (EOS1sc), see for example Battistelli et al (2020); Croucher and O’Sullivan (2008), to assess the true thermal potential in these ultra-high temperature environments, notably targeted in the NDDP and IDDP projects.

It is also worth noting that only the thermal energy flow rate was quantified in this study. In fact, the overall net thermal capacity and total efficiency of the system should be investigated, considering the pumping power required for fluid circulation. Other future work entails:

- The return flow pressure at the bottom of the wellbore should be validated with another experimental study or Multiphysics software.
- Exploring a variety of working fluids, including water with salinity, carbon dioxide (Sun et al, 2019), or isobutane as a supercritical fluid (Wang et al, 2019).
- Investigating more complex unconventional DBHE designs, such as an artificial geyser concept (Heller et al, 2014).
- Investigating the effects of anisotropic reservoir permeability/porosity on DBHE thermal recovery.
- An Economic analysis in the Newberry environment could also benefit the suitability of the DBHE design.

**Conclusion**

An in-depth sensitivity analysis was performed with reference to a base-case DBHE design from Morita et al (1992b), and was modelled into the NWG 55-29 Newberry environment.

The best-case scenarios that offered maximal thermal efficiency was: $\dot{m} = 5$ kg/s, an insulated inner tubing for Casg1 of $\lambda = 0.01038$ W/mK, maintaining a high $\lambda$ for the outer casings (Casg2, Casg3) and the cement layers (Ceme1, Ceme2) and increasing the inner annulus radius (Case2), with a resulting thermal output $q_{Th} = 1.50$ MW.

Each parameter change offered some interesting insights. Altering the mass flow rate influenced the working fluid’s velocity and its residence time down the annulus. An insulated inner tubing limits heat losses and minimises $\Delta T$ up the tubing. The outer casing properties do not significantly affect the heat transfer inside the wellbore, but should not be insulated to ensure sufficient heat transfer occurs between the reservoir and wellbore. The cement properties lead to a higher $q_{Th}$ when $\lambda$ was maximised and the use of graphite flakes in a conductive filler as opposed to conventional cement appears to be an efficient, though unproved concept, yielding a percentage increase in energy flow rate of 14.4% ($q_{Th} = 2.32$ MW). Adjusting the radii dimensions will affect the residence time of the working fluid, similar to the sensitivity analysis conducted for varying the mass flow rate.

An energy flow rate comparison was made between this study and the conventional NWG 55-29 EGS well. The results showed that the DBHE was a factor of 3.5 and 5.84 lower when assuming constant mass flow rates of 3 kg/s and 9 kg/s, respectively. While the DBHE design has a lower heat extraction and efficiency compared to conventional EGS designs, the initial energy consumption to stimulate an artificial reservoir is not needed and could be an ideal candidate for future EGS projects.
where issues like induced seismicity, fluid losses and contamination are mitigated. Future EGS projects should therefore consider the DBHE as an alternative design in situations where drilling may achieve original projects expectations.

Further work is needed to fully quantify the potential of the DBHE concept. The use of Multiphysics software and/or experimental data will be useful to validate the uncertainties in the pressure losses from the return fluid at the wellbore bottom. In addition, a variety of working fluid’s and unconventional DBHE designs should be explored. Numerical wellbore-reservoir modelling tools will need to be further developed for supercritical environments, using the IDDP and NDDP projects for initial verification and calibration.

Abbreviations
List of symbols
\( \kappa \): index for the working fluid; \( V \): volume (m\(^3\)); \( n \): outward normal vector; \( \Gamma \): surface area of well side (m\(^2\)); \( M^n \): mass accumulation term; \( F^n \): key mass/energy transport terms; \( q^n \): key source/sink terms; \( \phi \): porosity; \( S_l \): local saturation of phase; \( \rho \): density of phase (kg/m\(^3\)); \( \mu \): velocity of fluid (m/s); \( c \): specific heat capacity (J/kg/°C); \( T \): temperature (°C); \( U \): specific thermal energy in the phase; \( \lambda \): thermal conductivity (W/mK); \( h \): specific enthalpy in phase; \( (kJ/kg) \); \( k \): permeability (m\(^2\) or Darcy); \( \nu_{A,i} \): phase viscosity of the fluid (Pa seconds); \( P \): pressure (Pa); \( g \): gravitational acceleration (m/s\(^2\)); \( z \): elevation in well (m); \( \theta \): inclination angle of wellbore (°); \( \sigma \): cross sectional area of wellbore (m\(^2\)); \( C_0 \): profile parameter; \( j \): volumetric flux of mixture (m/s); \( K \): function to smooth transition of drift velocity from fluid stages; \( K_n \): Kutateladze number; \( m_i (\theta) \): inclination of wellbore; \( \gamma \): slip between two phases; \( f \): apparent friction coefficient; \( m_i \): mass flow rate (kg/s); \( r \): horizontal radii dimension (m); \( \Delta T \): change in temperature up tubing or down annulus (°C); \( q_{Ph} \): energy flow rate (MW).

Subscripts
\( \text{ph} \): phase; \( L \): liquid phase; \( G \): gaseous phase; \( R \): rock properties; \( a \): absolute permeability; \( r, ph \): relative permeability of a certain phase \( d \): drift velocity; \( c \): characteristic velocity; \( m \): mixture; \( i \): A annulus; \( T \): tubing; \( i \): inlet; \( i, A \): inner annulus; \( o \): outer tubing; \( i, T \): inner tubing; \( F \): working fluid at wellbore bottom.

Acronyms
DBHE: deep borehole heat-exchanger; EGS: Enhanced Geothermal System; SEGS: Supercritical Enhanced Geothermal System; NDDP: Newberry Deep Drilling Project; IDDP: Icelandic Deep Drilling Project; HDR: hot dry rock.

Acknowledgements
I would like to Acknowledge Dr Xiaolei Liu for initial assistance in T2Well/EOS1 software manipulation.

Author’s contributions
TR assisted in numerical validation section and general advice on journal layout. LP and TR assisted in T2Well/EOS1 software manipulation. All Authors have read and approved the final manuscript.

Funding
This research is supported by the UK Engineering and Physical Sciences Research Council (EPSRC) [Grant number EP/RS13222/1]

Availability of data and materials
The datasets generated and/or analysed during the current study are available in the [NAME] repository, [PERSISTENT WEB LINK TO DATASETS]

Competing interests
The authors declare that they have no competing interests.
