Abstract. We present the results of moderate resolution spectroscopy for a globular cluster in the M81 group dwarf spheroidal galaxy DDO 78. The DDO 78 globular cluster, 4 Milky Way globular clusters, spectroscopic and radial velocity standards were observed with the Long-slit spectrograph of the 6-m telescope (SAO RAS, Russia). Lick spectrophotometric indices were determined in the bandpasses adopted by Burstein et al. (1984). We have derived the mean metallicity of the globular cluster in DDO78 to be $[\text{Fe/H}] = -1.6 \pm 0.1$ dex by taking the weighted mean of metallicities obtained from the strength of several absorption features. We have estimated an age for the globular cluster of 9-12 Gyr similar to that found for the Galactic globular cluster NGC 362, which resembles our cluster by chemical abundance and integrated spectrophotometric properties.

Key words: galaxies: dwarf — galaxies: star clusters
Age and metallicity of a globular cluster in the dwarf spheroidal galaxy DDO 78

1. Introduction

The dominant type of dwarf galaxies in the local Universe is the dwarf spheroidal galaxies (DSphs). These systems are characterized by low luminosities ($M_V > -14$), low stellar density ($\mu_v(0) \gtrsim 22^m/\text{arcsec}^2$), small spatial extent (core radii < a few hundred parsecs), HI masses $M_{HI} \lesssim 10^5 M_\odot$, lack of current star formation (Grebel 2000, Stetson et al. 1998). New deep C-M diagrams and spectroscopy of individual red giants in several Local Group dSphs have shown us that, in spite of their current quiescent appearance, most of the systems have had surprisingly complicated evolutionary histories (Harbeck et al. 2002). It would be interesting to compare the chemical and star formation histories for DSphs in the Local group and in the other nearby groups. It is a difficult task, because the observational magnitude limit does not allow us to observe the HB stars in the galaxies at a distance of $> 3$ Mpc. Globular clusters (GCs) to be found in some DSphs are ideal probes of chemical histories and evolution of their host galaxies. They are bright enough to be observed at large distances. If the correlations between key spectral indices, metallicities and ages are common for GCs in all types of galaxies, we can determine the age for the given particular GC by using the evolutionary population synthesis models (e. g. Worthey 1994) and compare our results with the data available in literature on the Milky Way globular clusters.

The group of galaxies around the bright spiral M81 is one of the nearest prominent groups in the vicinity of the Local Group. It is situated at a distance of $\sim 3.7$ Mpc and consists of at least 12 DSphs and 12 dwarf irregular galaxies (Karachentsev et al. 2002). DDO 78 is one of the faintest DSphs of the group ($M_V = -12.83$). According to Karachentseva et al. (1987), DDO 78 has a very flat surface brightness profile with $\mu_{B(0)} =$
25.1"/μ", $r_{ef} = 32''$, and $B(t) = 15.8$. It was not detected in HI by Fisher & Tully (1981) and van Driel et al. (1998). An accurate distance modulus of DDO 78 is $(m - M)_0 = 27.85 \pm 0.15$ according to Karachentsev et al. (2000). The latter authors found globular cluster candidates in five dwarf spheroidal galaxies of the M81 group and measured their basic photometric parameters. The brightest globular cluster candidate in DSph galaxy DDO 78 has the integrated apparent magnitude $V_i = 19.45$, the integrated color after correction for Galactic reddening $(V - I)_0 = 1.07$, the angular half-light radius $R(0.5L) = 0.3''$, the central surface brightness $\mu_v(0) = 18.0^m/\mu''$, the linear projected separation of the globular cluster from the galaxy center 0.26 kpc. Sharina et al. (2001) measured a heliocentric radial velocity of the globular cluster candidate in DDO 78 to be $55 \pm 10$ km s$^{-1}$ by cross-correlation with template stars and established the object as a bona fide member of the galaxy. The present work continues our study of the dwarf spheroidal galaxies in the M81 group. The spectra of the globular cluster in DDO 78 (Fig.1) are of rather high signal-to-noise ratio and are suitable for the quantitative spectrophotometric study.

2. Observations and data reduction

The observations were performed with the Long-slit spectrograph UAGS (Afanasiev et al. 1995) at the prime focus of the 6-m telescope (SAO RAS, Russia) during 4 nights in January 2001 at a seeing of $\sim 1''$ (see Table 1 for details). An additional observation of stars from the Lick/IDS sample of Worthey et al. (1994) was performed in April 2002. The long-slit 130'' spectra were obtained with a CCD-detector having 1024x1024 pixels with 24x24 µm pixel size. For all observations we used a grating of 651 grooves/mm with a corresponding dispersion of 2.4 Å/pixel and a spectral resolution of 7-9 Å. The slit positions were chosen to cross the star cluster. The wavelength range was 4500-6900 Å. In all the cases the slit width was 2''. The scale along the slit was 0.41''/pixel. The reference spectra of Ar-Ne-He lamp were exposed before and after each observation to provide wavelength calibration. For velocity calibration we have obtained long-slit spectra of seven radial-velocity standard stars (Barbier-Brossat M. & Figon P. 2000) (see Table 1). The spectrophotometric standard stars BD28 4211, HZ44 and Feige34 (Bohlin 1996) were observed for flux calibration.

The data reduction was performed using the LONG package in MIDAS. The subsequent data analysis was also carried out in MIDAS. The primary data reduction included cosmic-ray removal, bias subtraction and flat-field correction. After wavelength calibration and sky subtraction, the spectra were corrected for atmospheric extinction and flux-calibrated. Then rows of every linearized two-dimensional spectrum were summed in the spatial direction to yield a final one-dimensional spectrum. All individual expo-
sures of the same object observed at the same night were then co-added to increase the S/N ratio.

In order to obtain integrated spectra for the Milky Way clusters (Fig.2), we averaged the spectra of different zones and individual stars in the core of each cluster. The sizes of the integrated apertures along the slit, equatorial coordinates of the GC centers and positional angles of the slit are listed in Table 2. All the spectra of the given particular GC were recorded at the same slit position across the center of the object.

Radial velocities of the globular clusters have been obtained by cross-correlation with template stars and were used for a subsequent abundance analysis. A comparison of the radial velocities measured by us with the corresponding values from Harris (1996) (Table 3, this paper) shows a good agreement.

3. Measurement of spectral indices and errors

Absorption-line indices were measured for each object according to the index definitions reported by Burstein et al. (1984). Each line index is a measurement of the flux, contained in the wavelength region centered on the feature relative to that contained in the red and blue "continuum" regions close to the features (Faber et al. 1977). We computed the index \( I \) as:

\[
I = -2.5 \log \left( \frac{F_1}{F_{C1} + k(F_{C2} - F_{C1})} \right),
\]

where \( F_1 \) is the mean flux in the feature, and \( F_{C1}, F_{C2} \) are the mean fluxes in the continuum bandpasses. \( k \) is a constant defined by interpolation between the central wavelengths in the blue and red bandpasses with respect to the central wavelength of the bandpass centered on the feature:

\[
k = \frac{(\lambda_{F_{C2}} - \lambda_{F_{C1}}) + (\lambda_{F_{C1}} - \lambda_{F_{C2}})}{(\lambda_{F_{C2}} + \lambda_{F_{C1}})}.\]

It is possible to convert the index values from the magnitudes to pseudo-equivalent widths and vice versa by the formulae:

\[
EW(I) = (\lambda_2 - \lambda_1)(1 - 10^{-\frac{I}{2.5}})
\]

\[
I(EW) = -2.5 \log(1 - \frac{EW}{\lambda_2 - \lambda_1}).
\]

We have derived the errors of the measurements of the line indices according to equations of Cardiel et al. (1998). The most common sources of systematic errors in the measurement of line-strength indices are: flux calibration effects, spectral resolution, sky subtraction uncertainties, scatter light effects, wavelength calibration and radial velocity errors, seeing and focus corrections, response deviations from linearity and random Poisson noise. We used a correlation between the measured absolute index error and the mean \((S/N\text{-ratio})/\text{Å}\) studied by Cardiel et al. (1998) to derive the error of our line-strength
index measurements. We computed the mean signal-to-noise ratio in each bandpass via the sum of the individual S/N ratios in each pixel:

$$SN(\text{Å}) = \frac{1}{N\sqrt{\theta}} \sum_{i=1}^{N} \frac{S(\lambda_i)}{\sigma(\lambda_i)},$$

where $\theta$ is the dispersion (in Å/pixel).

Two spectra of the globular cluster in DDO 78 were obtained during two nights under similar observational conditions (Table 1, Fig.1.). The final index values for the GC in DDO 78 (Table 5) are a weighted average of the indices from the two spectra using $\frac{1}{\sigma^2_i}$ as a weight. The final index photon errors, $\sigma_I$, are given by the reduced photon error:

$$\sigma_I = \left( \sum_{i=1}^{N} \frac{1}{\sigma^2_i} \right)^{-1/2}.$$

To check the calibration of our index measurements into the standard Lick system, we observed 4 stars from the list of Worthey et al. (1994). A comparison of the measured long-slit indices with those from Worthey et al. (1994) is given in Table 4 together with the measured indices of the twilight sky. The Lick indices of the twilight sky are known for us from the extensive observations with the Multi-Pupil Fiber Spectrograph of the 6 m telescope that are well calibrated into the standard Lick system through the careful monitoring of the standard stars (the last and most complete calibration of the MPFS index system into the standard Lick one can be found in Afanasiev & Sil’chenko 2002). One can see that our index system coincides with the standard Lick one within the errors of measurements. Besides the stars, we observed also the cores of 4 galactic clusters NGC 5272, NGC 2419, NGC 4147 and Pal 1 to compare them with the GC in DDO 78. The candidates for observations were chosen to conform to an expected metallicity of the globular cluster in DDO78. The measured indices in the Lick system for the globular clusters are listed in Table 5.

To investigate the properties of the GC in DDO78 we supplemented our data by observations of Cohen et al. (1998), Covino et al. (1995), Burstein et al. (1984), and Brodie and Huchra (1990) for galactic globular clusters, Huchra et al. (1996) for the Fornax dSph globular clusters and Schroder et al. (2002) for the M81 globular clusters. All observations were made in the Lick system. The data on $M_V$, $V$ and $I$ for the galactic GCs were taken from the catalog of Harris (1996).

4. Globular cluster metallicity and age

Metallicities for the observed GCs were calculated using the linear least-square fits of the indices versus metallicity for metallicity-sensitive line indices made by Covino et al. (1995). We obtained the mean metallicity of the cluster in DDO 78 and the mean
metallicities of Galactic GCs (Table 6) by taking the error-weighted average of the metallicities predicted by the strength of five metallicity-sensitive absorption-line indices: Mgb, Fe5270, Fe5335, Mg1, and Mg2. It should be noticed, that Mg1 and Mg2 each was assigned half weight, because these indices are tightly correlated (Burstein et al. 1984). A comparison of the indices measured by us for the core of the Milky Way GC NGC 5272=M3 with the corresponding values from Burstein et al. (1984) shows a good agreement. The estimates of [Fe/H] derived by us for Galactic GCs NGC 2419, NGC 4147, and M3 agree also rather well with the catalogue values: in the last column of Table 6 the estimates from Zinn & West are given for every cluster. As for Pal 1, whose metallicity given in Table 6 has been found by Rosenberg et al. (1998a), this cluster is known to be much younger than the bulk of other Galactic globular clusters (T(Pal1) = 6−8 Gyr, Rosenberg et al. 1998b); so the calibration of metallicity-sensitive indices made by using the old globular clusters is inapplicable to it. The value [Fe/H] = −1.6 ± 0.1 dex calculated in the present work for the GC in DDO78 does not contradict the mean metallicity of the galaxy itself derived from the red giant branch morphology by Karachentsev et al. (2000), [Fe/H] = −1.6 ± 0.3 dex.

Fig. 3a shows the index \( \langle \text{Fe} \rangle = \frac{(\text{Fe}5270 + \text{Fe}5335)}{2} \) as a function of the index Mgb. It is evident that the GC in DDO78 follows well Worthey models and is similar to the galactic globular clusters on this diagram. A comparison of the metallicity-sensitive indices with the corresponding values for the Galactic GC with [Fe/H] ∼ −1.6 dex shows a good agreement. In Fig. 3b, 3c, and 3d we plot the strengths of Mg2, Mgb, and \( \langle \text{Fe} \rangle \) as a function of [Fe/H]. The low-metallicity Galactic and M81 GCs and GC in DDO78 occupy generally the same positions in these Figures.

We continue our analysis by plotting various indices as a function of \((V-I)\) color corrected for extinction, adopting the photometry of Karachentsev et al. (2000) for the globular cluster in DDO78. Fig. 4a, 4b, 4c, and 4d show \((V-I)_0\) color versus Mgb, Mg2, \(\langle \text{Fe} \rangle\) and [Fe/H]. It is clear that the GC in DDO78 falls rather into a group of low-metallicity Galactic GGs. However, its \((V-I)_0\) color seems to be too red.

\((V-I)_0\) colors for M81 GCs were computed from \((B-V)\) colors derived by Schroder et al. (2002) and corrected for foreground reddening and for the mean value of internal reddening in M81 computed by the latter authors. We used the relationship between intrinsic \((B-V)\) and \((V-I)\) colors for Milky Way GCs with the integrated spectral type F9/G0-G2 from Reed et al. (1988).

To obtain the age of the GC in DDO78 we plot the age-sensitive index Hß against Mgb (Fig. 5a), Mg2 (Fig. 5b), \(\langle \text{Fe} \rangle\) (Fig. 5c), and [Fe/H] (Fig. 5d). The signs are the same as in the previous figures.
Fig. 5 demonstrates that the GC in DDO 78 has a too low $\text{H} \beta$ for its weak metal absorption lines: it falls below the oldest model sequence, $T = 17$ Gyr. However, it is not a single outlier: the whole group of the Galactic globular clusters with red horizontal branches, mostly of intermediate metallicity, are also well below the 17-Gyr model sequence of Worthey (1994). The problem is not our finding: Covino et al. (1995), comparing their index measurements for Galactic globular clusters with the models of Buzzoni et al. (1992, 1994), which included an EMPIRICAL RED horizontal branch, have also found the same shift. They have suggested that this discrepancy results from the solar $\alpha/\text{Fe}$ ratio of the models: if one takes $\alpha$-enhanced isochrones, the isochrone turn-off points would be redder (cooler), and the corresponding $\text{H} \beta$ equivalent widths would be lower. Since the Galactic globular clusters are known to have $[\text{O}/\text{Fe}] = +0.3 \pm 0.5$, their suggestion seemed to be the solution. However, during the last years, there were numerous attempts to improve model isochrones and evolutionary synthesis approach to the globular clusters, and none of them gives anything to correct the discrepancy of Fig.5. Salaris and Weiss (1998) have demonstrated their new $\alpha$-enhanced isochrones, from which one can see that for the intermediate metallicity, $[\text{Fe/H}] = -1.35$ dex, the $\alpha$-element enhancement affects the slope of the giant branch on the C-M diagram, but leaves the main-sequence turn-off position unaffected. Maraston (1998) (see also Maraston et al. 2001) has revised the $\text{H} \beta$ estimates by evolutionary synthesis with new isochrones and the fuel-consumption theorem application to the horizontal branch treatment, but her $\text{H} \beta$ indices are even higher than those of Worthey (1994) and Buzzoni et al. (1992, 1994).

So, a conclusion must be made that up to now state-of-art models cannot explain some intermediate-metallicity globular clusters, namely, almost all the clusters with red horizontal branches. Under such circumstances the only reasonable way to determine the age of the GC in DDO 78 is to compare it with any particular Galactic globular cluster for which a detailed C-M diagram is available. The nearest neighbor of the GC in DDO 78 in Fig.5 is a well-studied Galactic globular cluster NGC 362. While the metallicities of the most globular clusters with red horizontal branches are higher than $[\text{Fe/H}] = -1$ dex, the metallicity of NGC 362 is only slightly higher than that of the GC in DDO 78, namely, its $[\text{Fe/H}] = -1.33 \pm 0.01$ dex (Shetrone & Keane 2000), and it is a member of the classical second-parameter cluster pair NGC 288/NGC 362. These two clusters have the same metallicities, but quite different morphologies of the horizontal branches, the horizontal branch of NGC 362 being a red one. After a long discussion about the nature of the second parameter determining a morphology of the horizontal branches, a common view is established that it may be an age; in particular, a careful examination of the C-M diagrams of NGC 288 and NGC 362 by Bellazzini et al. (2001) and Catelan et al. (2001) has proved that the latter cluster is younger by 1.5–2 Gyr than the former.
As for the estimates of the absolute age of NGC 362, they range from 8.7 Gyr (Salaris & Weiss 1998) and 9.9 Gyr (Carretta et al. 2000) to 11–12 Gyr (Vandenberg 2000). Since the differences of Hβ, Mg2, Mgb, and ⟨Fe⟩ indices between NGC 362 and GC in DDO 78 are practically within the observational errors, we can suggest that the age of the GC in DDO 78 is also about 9–12 Gyr.

5. Discussion

According to Burgarella et al. (2001) the mean metallicity of metal-poor globular cluster systems is weakly dependent on the host galaxy’s properties and is almost ”universal” at [Fe/H] ∼ −1.4 ± 0.3 dex. The metallicity of the GC in DDO78 [Fe/H] = −1.6 ± 0.1 dex agrees well with this value. There are two DSph companions of the Milky Way which contain globular clusters: Fornax and Sagittarius DSph galaxies. Fornax DSph has the absolute integral magnitude $M_V = -13.7$, and the distance from the Milky Way 140 kpc (van den Bergh 2000). These properties are comparable to those of DDO 78, which is located at the distance of 223 kpc from M81 (Karachentsev et al. 2002). Five Fornax DSph globular clusters have the mean metallicity [Fe/H] = −2.04 dex, essentially the same ages ( | δt |< 1 Gyr) and are coeval with the old, metal-poor clusters of our Galaxy (Buonanno et al. 1998) Unfortunately, there are no measured integrated absorption indices for all Fornax GCs in the literature. Fornax DSph GCs 3 and 5 show absorption feature strengths (Huchra et al. 1996) unlike those for the GC in DDO78. Our cluster seems to be more metal-rich than the Fornax DSph GCs. We found only one Galactic globular cluster with measured integral absorption indices, NGC 362, which resembles the GC in DDO78 by all properties within the errors. NGC 362 has the galactocentric radius $R_{gc} = 9.2$ kpc, the integral absolute visual magnitude $M_V = -8.4$ and resembles by its properties some intermediate-metallicity clusters with $R_{gc} > 8$ kpc, Pal 12, NGC 1851, NGC 1261, NGC 2808 (Rosenberg et al. 1999). These clusters are younger by ∼ 2 Gyr than the metal-poor halo GCs and are associated with so-called 'streams' that may be relics of ancient Milky Way satellites which had masses typical of a dwarf galaxy.

The M81 group of galaxies has a similar to the LG structure (Karachentsev et al. 2000). The subgroups around the Sb type galaxies, the Milky Way and M31, have a spatial separation of ∼ 1 Mpc and approach to each other at a velocity of ∼ 130 km s$^{-1}$. Such a situation resembles the M81/NGC 2403 complex. But there are some differences between the two groups. The core members of the M81 group: M81, M82, NGC 3077 and NGC 2976 are known to be closely interacting from the aperture synthesis maps of the 21 cm H I emission (Yun et al. 1994, Boyce et al. 2001). The dwarf spheroidal galaxies are distributed around M81 asymmetrically (Karachentsev et al. 2001). With respect to
the group centroid (located between M81 and M82) all DSphs are concentrated in one quadrant. Jonson et al. (1997) reported about the discovery of the high-excitation HII region in K61, the brightest DSph galaxy of the M81 group and the closest companion to M81. They found the metallicity of HII region, Z, between 0.001 and 0.008, and the age between 2 and 5.2 Myr. The properties of DSph galaxies appear to be correlated with the galaxy mass and with environment. Does the tidal interaction between the brightest M81 group galaxies influence the distribution and star formation histories of DSphs? Accurate numerical simulations are needed.

Fig. 1. Two spectra of the globular cluster in DDO78 obtained on 18.01.2001 (top) and on 19.01.2001 (bottom).

Fig. 2. Spectra of Galactic globular clusters NGC5272, NGC2419, NGC4147.
Fig. 3. \( \langle \text{Fe} \rangle = (\text{Fe}5270 + \text{Fe}5335)/2 \) plotted against Mgb index (Fig. 3a); also we show [Fe/H] correlations with the metallicity-sensitive indices Mg2 (Fig. 3b), Mgb (Fig. 3c), and \( \langle \text{Fe} \rangle \) (Fig. 3d) for the observed globular clusters (signs marked on the plot), for Milky Way (grey dots), M81 (dark small dots) and Fornax DSph globular clusters (open circles). Typical errors for the M81 clusters are shown with the long bars; for Galactic clusters, with the short bars. The ages of the Worthey’s (1994) models are given in gigayears. The
