(Dated: November 15, 2010)

Neutron and x-ray diffraction studies of Ba(Fe$_{1-x}$Mn$_x$)$_2$As$_2$ for low doping concentrations ($x \leq 0.176$) reveal that at a critical concentration, 0.102 $< x < 0.118$, the tetragonal-to-orthorhombic transition abruptly disappears whereas magnetic ordering with a propagation vector of $(\frac{1}{2} \frac{1}{2} 0)$ persists. Among all of the iron arsenides this observation is unique to Mn-doping, and unexpected because all models for "stripe-like" antiferromagnetic order anticipate an attendant orthorhombic distortion due to magnetoelastic effects. We discuss these observations and their consequences in terms of previous studies of Ba(Fe$_{1-x}$TM$_x$)$_2$As$_2$ compounds ($TM =$ Transition Metal), and models for magnetic ordering in the iron arsenide compounds.

PACS numbers: 74.70.Xa, 75.25.-j, 74.25.Dw

Recent systematic neutron and x-ray diffraction studies of underdoped Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ superconductors have revealed fascinating results regarding the interactions among structure, magnetism and superconductivity. The undoped $A$Fe$_2$As$_2$ parent compounds ($AE =$ Ba, Sr, Ca) manifest simultaneous transitions from a high-temperature paramagnetic tetragonal phase to a low-temperature orthorhombic antiferromagnetic (AFM) structure. Upon doping with Co for Fe in Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$, both the structural ($T_S$) and AFM ordering ($T_N$) are suppressed to lower temperatures and split, with $T_S$ slightly higher than $T_N$. Neutron and x-ray studies have clearly established that both the magnetic and orthorhombic distortion are sensitive to superconductivity throughout the Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ series. At a given Co-composition, as the sample temperature is reduced below the superconducting transition ($T_c$), there is a clear suppression of the magnetic order parameter, and reentrance into the paramagnetic phase is observed for a Co-doping concentration of $x \approx 0.059$. Similarly, the magnitude of the orthorhombic lattice distortion decreases below $T_c$ and reentrance into the tetragonal structure was observed for $x \approx 0.063$. This striking behavior for Ba(Fe$_{1-x}$Co$_x$)$_2$As$_2$ has been related to the strong coupling between superconductivity and magnetism as well as an unusual magnetoelastic coupling that arises from emergent nematic order in the iron arsenides. The separation of $T_S$ and $T_N$ and suppression of the magnetic order parameter below $T_c$ have been confirmed for electron-doped Ba(Fe$_{1-x}$Rh$_x$)$_2$As$_2$ and Ba(Fe$_{1-x}$Ni$_x$)$_2$As$_2$ as well.

In strong contrast to what is found for the electron-doped $A$Fe$_2$As$_2$ compounds, hole doping on the Fe site through the introduction of Ca or Mn has, so far, failed to produce superconducting samples for any doping level, although superconductivity is realized by hole-doping through the substitution of K for the $AE$. This indicates that the number of additional electrons (or holes) is not the sole controlling factor for superconductivity. Furthermore, unlike the suppression and eventual elimination of magnetic ordering with increasing $x$ found for electron-doped compounds, recent neutron studies of BaFe$_{1-x}$Cr$_x$)$_2$As$_2$ indicate that, for $x \geq 0.30$, the "stripe-like" AFM structure is replaced by the G-type "checkerboard-type" structure as found for BaMn$_2$As$_2$ and proposed for BaCr$_2$As$_2$. Given the strong coupling between structure, magnetism and superconductivity already established for the iron arsenides, such differences in magnetic and structural behavior in hole-doped materials demand attention.

Here we report on neutron and x-ray diffraction studies, together with resistance measurements, of Ba(Fe$_{1-x}$Mn$_x$)$_2$As$_2$ for low doping concentrations ($x \leq 0.176$). We find that within a critical concentration range, 0.102 $< x < 0.118$, the tetragonal-to-orthorhombic transition abruptly disappears while magnetic ordering with a propagation vector of $(\frac{1}{2} \frac{1}{2} 0)$ persists along with changes in the temperature evolution of the AFM ordering. The presence of "stripe-like" AFM order in the absence of the orthorhombic distortion is unanticipated, and holds important consequences for models of magnetic ordering in the iron arsenides.

Single crystals of Ba(Fe$_{1-x}$Mn$_x$)$_2$As$_2$ ($0 < x < 0.176$) were grown out of a FeAs self-flux using conventional high-temperature solution growth. Each sample was measured at between 10 and 20 positions using wavelength dispersive spectroscopy (WDS) to determine the Mn-doping composition, $x$, with an uncertainty of 5%. All samples used for the neutron and x-ray measurements exhibited small mosaicities ($< 0.02^\circ$ full-width-at-half-maximum [FWHM]) measured by x-ray rocking scans, demonstrating excellent sample quality. Temperature-dependent AC electrical resistance data ($f = 16$ Hz, $I = 3$ mA) were collected in a Quantum Design Magnetic Properties Measurement System using a LR700 resistance bridge. In Fig. 1 we show the resistance data (solid symbols) normalized to their room temperature values, and the their temperature derivatives (open symbols) for a representative subset of three compositions, $x = 0.074, 0.102$ and 0.118. A sharp anomaly, characteristic of all samples for $x \leq 0.074$ is found at approximately 80 K for $x = 0.074$, which broadens and shifts to lower temperature for $x = 0.102$ and then to higher temperature for $x = 0.118$. If we associate these features with magnetic and/or structural transitions, the non-monotonic behavior of the characteristic temperature is highly unusual for the iron arsenides. Only a single feature
is observed in the derivative curve indicating that the magnetic and structural transitions are likely coincident in temperature, and superconductivity is absent in all samples for $T \geq 2$ K.

High-resolution, single-crystal x-ray diffraction measurements were performed on a four-circle diffractometer using Cu $K_{\alpha1}$ radiation from a rotating anode x-ray source, selected by a germanium (1 1 1) monochromator. The diffraction data were obtained between room temperature and 6 K, the base temperature of the closed-cycle diaplex refrigerator. Neutron diffraction measurements were performed on the HB1A diffractometer at the High Flux Isotope Reactor at Oak Ridge National Laboratory. The experimental configuration was 48°- 40°- 40°-136° with fixed incident neutron energy of 14.7 meV, and two pyrolytic graphite filters for the elimination of higher harmonics in the incident beam.

The principal results of our scattering studies are summarized in Figs. 2 and 3 for a representative subset of the compositions, $x = 0.074, 0.102$ and 0.118. The neutron diffraction data in Figs. 2(a) and (b) show the magnetic Bragg peak at $(1 \over 2 1 \over 2 3)$ (using indices referenced to the high-temperature tetragonal unit cell) for both $x = 0.102$ and $x = 0.118$, consistent with the "stripe-like" AFM order found for the iron arsenide compounds. However, the x-ray data in Figs. 2(c) and (d) demonstrate that the orthorhombic distortion, evident from the splitting of the (1 1 10) charge peak for the $x = 0.102$ composition, was not observed for $x = 0.118$. Figure 3 displays the temperature evolution of the magnetic order, measured by neutron diffraction, and the orthorhombic distortion, measured by x-ray diffraction, for these same compositions. The integrated intensity of the magnetic scattering (filled circles) was measured at the $(1 \over 2 1 \over 2 3)$ magnetic Bragg position as the sample angle was scanned [see Figs. 2(a) and (b)]. The orthorhombic distortion, $\delta$, was calculated from the splitting of peaks observed in $(\xi \xi 0)$-scans through the (1 1 10) Bragg peak [see Fig. 2(c) and (d)]. For samples with $x \leq 0.074$ [Fig. 3(a)], we observe well defined AFM and structural transitions that are, within our resolution, coincident in temperature. For $x = 0.102$ [Fig. 3(b)], a weak "tail" of magnetic scattering extends to temperatures above the structural transition and, for $x \geq 0.118$, the structural transition is absent (the sample remains tetragonal down to at least $T = 6.4$ K within our resolution for $\delta$ of $1 \times 10^{-4}$) and the temperature evolution of the AFM order is quite different from what is observed for $x = 0.074$. For $x \geq 0.118$, a distinct broadening of the magnetic peak beyond the resolution of our measurement is observed for temperatures above $T^*$, as defined below and in the insets to Figs. 3(b) and (c).

In Fig. 4(a) we have used the neutron, x-ray and resistance data to construct a phase diagram in the low Mn-doping regime for Ba(Fe$_{1-x}$Mn$_x$)$_2$As$_2$. The phase line between the paramagnetic/tetragonal and AFM/orthorhombic phase for $x \leq 0.074$ was easily determined from the well-defined onset of the distortion and the appearance of a resolution limited magnetic Bragg peak at $(1 \over 2 1 \over 2 3)$. For $x \geq 0.102$, however, the

FIG. 1: (Color online) Resistance, normalized to the value at $T = 300$ K, and the temperature derivative of the resistance ratio for the $x = 0.074, 0.102$ and 0.118 samples. Lines are guides to the eye.

FIG. 2: Neutron diffraction rocking scans through the (1/2 1/2 3) magnetic Bragg peak above (open squares) and below (filled circles) the AFM order found for the iron arsenide compounds. Note the splitting for the $x = 0.118$ sample and its absence for $x = 0.102$, however, the
onset of long-range magnetic order is more difficult to identify. Therefore, we have defined a characteristic temperature, \( T^* \), which denotes the temperature below which the width of the magnetic peak is limited by our instrumental resolution (approximately 0.3\(^\circ\) FWHM). We note that the values of \( T^* \) follow the same trend seen for the maxima in \( \frac{dI}{d\theta} \) in Fig. 1. The gray band in the phase diagram represents the temperature range, above \( T^* \), where magnetic scattering at \( (\frac{1}{2} \frac{1}{2} \frac{3}) \) persists [See Figs. 3(b) and (c)].

In Fig. 4(b) we plot the measured structural distortion and the magnetic moment per Fe/Mn site, extrapolated to \( T = 0 \) as described in our previous work as a function of doping concentration. Several interesting comparisons can be made between these results and previous x-ray and neutron scattering studies of \( \text{Ba(Fe}_{1-x}\text{Co}_x\text{)}_{2}\text{As}_2 \). First, we note that our data for \( \text{Ba(Fe}_{1-x}\text{Mn}_x\text{)}_{2}\text{As}_2 \) for \( x \leq 0.074 \) unambiguously show that the structural and magnetic transitions remain locked together, unlike the separation of the structural and AFM transitions found for Co-doping. Furthermore, at \( x = 0.102 \), we find a broadened magnetic peak at \( (\frac{1}{2} \frac{1}{2} \frac{3}) \) above the structural transition and, for \( x \geq 0.118 \), we observe the magnetic Bragg peak at \( (\frac{1}{2} \frac{1}{2} \frac{3}) \) in the absence of an orthorhombic distortion, a surprising observation that will be discussed below. Finally we note that the magnetic moment per Fe/Mn site as well as the magnitude of the structural distortion vary only weakly with composition for \( x \leq 0.102 \) whereas, for Co-substitution, the suppression of the magnetic moment and structural distortion with doping is much more severe.

It is also useful to compare these results to what has recently been found for \( \text{Ba(Fe}_{1-x}\text{Cr}_x\text{)}_{2}\text{As}_2 \). At much higher Cr concentrations, \( x \geq 0.30 \), Ref. 24 reports that the “stripe-like” magnetic structure is replaced by G-type, “checkerboard,” magnetic order as shown by polarized and unpolarized neutron diffraction measurements of the integrated intensity of the \((1 0 1)\) Bragg peak (Fig. 3 in Ref. 24). G-type AFM order has been proposed for the parent \( \text{BaCr}_2\text{As}_2 \) compound and measured for \( \text{BaMn}_2\text{As}_2 \) so it is not unreasonable to expect this change in magnetic structure at high enough Cr-, or Mn-, doping. However, our unpolarized neutron diffraction measurements of the \((1 0 1)\) peaks for the highest Mn concentrations, \( x = 0.147 \) and \( x = 0.176 \), find no evidence of G-type ordering below \( T = 300 \text{ K} \). More specifically, we
find no significant change in the (1 0 1) peak between 12 K and 300 K. We can not exclude G-type ordering that develops well above room temperature given the high ordering temperature of the parent compound\textsuperscript{25} but view this as unlikely in light of the substantial dilution of Mn in our samples. For both Cr- and Mn-doping, the moment per Fe-site remains constant (Cr), or decreases only weakly (Mn) with increasing concentration up to \( x \approx 0.20 \). Indeed, as the dashed line in Fig. 2b shows, the decrease in the measured moment is consistent with the decreasing Fe concentration implying that the Mn moment does not contribute to the magnetic AFM order characterized by the \((\frac{1}{2} \frac{1}{2} 1)\) propagation vector. Furthermore, for Mn-doping we find an increase in the characteristic temperature \( (T^*) \) associated with magnetic ordering with this propagation vector for \( x > 0.102 \), whereas for Cr-doping, the ordering temperature for this propagation vector continues to decrease until the transition is completely suppressed at \( x = 0.335 \) where the G-type AFM structure is observed\textsuperscript{26}. All of this points to interesting differences in the phase diagrams between Ba(Fe\textsubscript{1-x}Mn\textsubscript{x})\textsubscript{2}As\textsubscript{2} and Ba(Fe\textsubscript{1-x}Cr\textsubscript{x})\textsubscript{2}As\textsubscript{2}.

The observation of a magnetic structure characterized by a propagation vector of \((\frac{1}{2} \frac{1}{2} 1)\) in the absence of an orthorhombic distortion (for \( x > 0.102 \)) is very surprising and unique to Ba(Fe\textsubscript{1-x}Mn\textsubscript{x})\textsubscript{2}As\textsubscript{2} among the iron arsenides; models for "stripe-like" AFM order in the iron arsenides anticipate an attendant orthorhombic distortion due to magnetoelastic effects\textsuperscript{27–29}. Furthermore, this observation is difficult to reconcile with current theories that promote orbital ordering\textsuperscript{25} as the driving force for the "stripe-like" magnetic phase and the orthorhombic distortion. A second key result of this study is the qualitative change in the temperature dependence of the magnetic ordering for compositions in excess of \( x = 0.102 \) and the distinct broadening of the magnetic peak for \( T > T^* \). At this point it is not clear whether the scattering above \( T^* \) for \( x > 0.102 \) is purely elastic or has a quasielastic component within the finite energy window of our neutron measurements, a point that should be investigated further.

The change in the temperature dependence of the magnetic peak points to a strong perturbation of the magnetic ordering, perhaps through disorder effects associated with the introduction of the more localized Mn moments. Furthermore, the abruptness of this change with composition (over a narrow range of \( \Delta x < 2\% \)) offers the intriguing possibility that the magnetic structure of Ba(Fe\textsubscript{1-x}Mn\textsubscript{x})\textsubscript{2}As\textsubscript{2} is modified for \( x > 0.102 \). In recent theoretical work, Eremin and Chubukov\textsuperscript{29} point out that a generic spin configuration for the magnetic iron layers has the form, \( \Delta_1 e^{iQ_1 R} + \Delta_2 e^{iQ_2 R} \), where \( \Delta_1 \) and \( \Delta_2 \) correspond to two order parameters for ordering at wavevectors \( Q_1 = (0, \pi) \) and \( Q_2 = (\pi, 0) \), respectively, in the unfolded Brillouin zone. The observed "stripe-like" magnetic structure occurs when \( \Delta_1 = 0 \) and \( \Delta_2 \parallel Q_2 \). However, when they consider a coupling between the second hole pocket at the \( \Gamma \) point with the elliptical electron pocket at \((0, \pi)\), a two-Q structure with both \( \Delta_1 \neq 0 \) and \( \Delta_2 \neq 0 \) can emerge. For \( \Delta_1 \perp \Delta_2 \) and \(|\Delta_1| = |\Delta_2|\), this two-Q structure does not break the tetragonal symmetry and, therefore, does not yield an orthorhombic distortion of the lattice, consistent with our results. Because of the presence of magnetic domains in the tetragonal phase, magnetic peaks for the "stripe-like" and two-Q AFM structures can not be distinguished.
