Abstract
Central venous cannulation is the most common procedure performed in perioperative setting and intensive care unit. Many case reports reported unusual positioning of central line catheters. Here, we would like to report a case of central line path in persistent left superior vena cava, a rare entity with a course similar to the right internal jugular central line. Preoperative computed tomography chest showed duplex superior vena cava which was not reported.

Introduction
Left-sided superior vena cava (SVC) occurs in 0.3–0.5% of the general population and in 5% of those with congenital heart defects. Persistent left superior vena cava (PLSVC) is the most common congenital malformation of thoracic venous return [1]. Most patients are asymptomatic. In approximately 10–20% of cases, it is associated with drainage to the left atrium [1]. Most of the time, the presence of vessel is identified incidentally during central line placement as in our case or by computed tomography (CT)-chest. Written consent was obtained from the family of the patient.

Case Report
A 45-year-old male patient without comorbidities with the history of necrotizing pancreatitis posted for exploratory laparotomy. The preoperative vitals were stable. The patient had CT-chest and abdomen preoperatively with reports mostly concentrated on the abdomen. The patient had left internal jugular cannulation inserted using ultrasound in the first attempt with ease for inotrope and total parenteral nutrition. Surgery was uneventful; the patient was shifted to intensive care unit on ventilator support for further management. A chest X-ray done postoperatively revealed unusual course (Fig. 1), just like the straight course as in the right side. All ports have free venous blood, confirmed by blood gas analysis. Later, we consulted a radiologist who reported double SVC, which was not reported in previous CT-chest (Fig. 2). The patient was stable throughout in the intensive care unit.

Malpositioning of Left Internal Jugular Central Line

As per information furnished by the family, the patient never had any cardiac signs and symptoms. The line was changed to the right internal jugular central line to measure the central venous pressure as it was unreliable on the left side on day 3 (Fig. 3). The insertion of right central line was uneventful. Postoperative trans-thoracic echocardiography was done, which did not reveal any cardiac anomalies.

Discussion

A left-sided SVC is an incidental finding found usually during central line insertion as per our case. It forms during normal foetal development due to failure of obliteration of anterior cardiac vein [2]. The PLSVC passes anterior to the left hilum and lateral to aortic arch. Most commonly, this vein drains into coronary sinus 82–90% can be seen in our patient CT-chest (Fig. 2) and left atrium in 8%.

As far as concerned, it is safe to use central line for drug administration not for central venous pressure measurement. Other complications resulting from the existence of PLSVC include difficulty in pulmonary artery catheterization, cerebral abscess, arrhythmia, and thromboem-
bolic events [3–5]. It is also worth mentioning that the incidence of defects in foetuses is higher than in the general population. This is due to the anatomical anomalies that may cause spontaneous miscarriage, as well as the existence of PLSVC along with other heart defects that may lead to premature death [4, 6].

The most common congenital heart diseases associated with left SVC are Tetralogy of Fallot, anomalous pulmonary vein, and coarctation of aorta [1]. It was an incidental finding during the procedure as our patient was asymptomatic and even the vein was draining into the coronary sinus as seen in the CT-chest (Fig. 2). The differential diagnoses of the left para-mediastinal catheter are PLSVC, left superior intercostal vein, and left pericardio-phrenic vein. The malposition is usually noticed during left central line insertion. It is of utmost importance to us to identify such unusual path and to identify any co-existing cardiac abnormalities if suspected. PLSVC is very often discovered accidentally during invasive cardiac procedures, mostly during routine left-sided right-heart catheterization and surgical procedures [7]. Malpositioning of the central line like kinking inside the internal jugular vein, migration to the subclavian vein, and the external jugular vein has been reported [8, 9].

Conclusion

The abnormal path taken by the central line in view of PLSVC is an incidental finding during central line insertion, which is safe to administer lifesaving drugs. It is unreliable for central venous pressure measurement. We should always rule out congenital cardiac anomalies in such patients by transoesophageal echocardiography by cardiac MRI. There are many cases where the central line has taken unusual malpositioning in both left and right internal jugular cannulation, but PLSVC is a concern in view of deranged haemodynamics in small percentage of patients which need to be addressed appropriately in perioperative period.
