Abstract
The structure, linear stability, and dynamics of localized solutions to singularly perturbed reaction–diffusion equations have been the focus of numerous rigorous, asymptotic, and numerical studies in the last few decades. However, with a few exceptions, these studies have often assumed homogeneous boundary conditions. Motivated by the recent focus on the analysis of bulk-surface coupled problems, we consider the effect of inhomogeneous Neumann boundary conditions for the activator in the singularly perturbed one-dimensional Gierer–Meinhardt reaction–diffusion system. We show that these boundary conditions necessitate the formation of spikes that concentrate in a boundary layer near the domain boundaries. Using the method of matched asymptotic expansions, we construct boundary layer spikes and derive a class of shifted nonlocal eigenvalue problems analogous to those studied in Maini et al. (Chaos 17(3):037106, 2007) for which we rigorously prove partial stability results. Moreover, by using a combination of asymptotic, rigorous, and numerical methods we investigate the structure and linear stability of selected one- and two-spike patterns. In particular, we find that inhomogeneous Neumann boundary conditions increase both the range of parameter values over which asymmetric two-spike patterns exist and are stable.

1 Introduction

Originally proposed by Gierer and Meinhardt in 1972, the Gierer–Meinhardt (GM) model illustrates the pattern forming potential of two mechanisms: local self-activation and lateral inhibition (Gierer and Meinhardt 1972). In the original GM model, two diffusing chemical species, an activator and inhibitor, interact through prescribed reaction kinetics. Specifically, letting $u$ and $v$ denote the concentrations of the activator and inhibitor, respectively, the GM model takes the form of the two-component reaction–diffusion system

\[
\begin{align*}
  u_t &= D_u \Delta u - u + u^p v^{-q}, & x \in \Omega, \\
  v_t &= D_v \Delta v - v + u^r v^{-s}, & x \in \Omega,
\end{align*}
\]

(1.1a)

where it is assumed that the exponents $(p, q, m, s)$ satisfy

\[
 p > 1, \quad q > 0, \quad r > 0, \quad s \geq 0, \quad \text{and} \quad p - 1 - (s + 1)^{-1}qr < 0.
\]

and homogeneous Neumann boundary conditions are typically imposed. As is evident from the choice of reaction kinetics, the GM model describes a process of self-activation, or auto-catalysis, by the activator and lateral inhibition by the inhibitor. In addition, the spatially homogeneous steady state $(u, v) = (1, 1)$ undergoes a spontaneous symmetry breaking bifurcation into a patterned state through a Turing instability when $D_u/D_v$ is sufficiently small. While one of the early applications of the GM model was specifically to head generation and regeneration in Hydra (Gierer and Meinhardt 1972), self-activation and lateral inhibition are considered to be important pattern formation mechanisms in general biological systems and this has been supported by the identification of several molecular candidates for the activator and inhibitor in activator-inhibitor systems (Meinhardt and Gierer 2000).

In the singularly perturbed limit of an asymptotically small diffusivity ratio $D_u/D_v = \mathcal{O}(\varepsilon) \ll 1$, a classical Turing stability analysis of (1.1a) reveals an asymptotically large band of unstable spatial modes. In this singularly perturbed limit, the GM system, as well as numerous other two-component reaction–diffusion systems, is known to exhibit multi-spike patterns in which the activator concentrates at a discrete collection of asymptotically small regions. The rich structural and stability properties of these multi-spike patterns have been the focus of extensive asymptotic, rigorous, and numerical studies over the past two decades (Wei 1999; Iron et al. 2001; Doelman et al. 2001; Wei and Winter 2014; Ward 2018). While boundary conditions have been identified as playing an important role in pattern formation (Maini et al. 1997; Dillon et al. 1994), relatively few studies have investigated the role of boundary conditions on the structure and stability of multi-spike solutions to singularly perturbed reaction–diffusion systems. Instead, most such studies have assumed either homogeneous Neumann or homogeneous Dirichlet boundary conditions. Notable exceptions include the investigation of homogeneous Robin boundary conditions for the activator in the GM model (Berestycki and Wei 2003; Maini et al. 2007) and inhomogeneous Robin boundary conditions for the inhibitor in the two-dimensional Brusselator model (Tzou and Ward 2018). These two studies and their illustration of the effect of boundary conditions on the structure and stability of multi-spike patterns serve as the primary
motivation for the present paper in which we consider inhomogeneous Neumann boundary conditions for the activator in the one-dimensional singularly perturbed GM model. Additionally, this paper aims to address some of the technical issues that arise in bulk-surface coupled reaction–diffusion systems for which inhomogeneous boundary conditions naturally arise (Levine and Rappel 2005; Rätz and Röger 2014; Madzvamuse et al. 2015; Gomez et al. 2019).

To simplify the presentation in this paper, we consider the singularly perturbed one-dimensional GM model with exponents \((p, q, r, s) = (2, 1, 2, 0)\). Different exponents result only in quantitative rather than qualitative differences provided that they satisfy (1.1b) in addition to some existence and stability constraints. Specifically, for the existence of spiky solutions when \(\Omega\) is an \(n\)-dimensional domain it is generally required that \(1 < p < \frac{n+2}{n-2}\) if \(n \geq 3\) and \(1 < p < \infty\) if \(n \leq 2\), while for the stability analysis it is required that \(1 < p \leq 1 + \frac{2}{n}\) (Wei 1999, 2008). For both a formal and rigorous analysis of spike solutions with such general GM exponents, we refer to (Wei 1999; I r o n e t al. 2001; Ward and Wei 2003) as well as the book (Wei and Winter 2014) and the references therein. After possibly rescaling the spatial variable in (1.1a), we assume that the domain is the unit interval \(\Omega = (0, 1)\) and that \(D_u = \varepsilon^2\) while \(D_v = O(1)\) where \(\varepsilon \ll 1\) is an asymptotically small parameter. We then impose the inhomogeneous Neumann boundary conditions

\[-\varepsilon^2 u_x(−1, t) = A \quad \text{and} \quad \varepsilon^2 u_x(1, t) = B\]

but maintain that the inhibitor have homogeneous Neumann boundary conditions. Seeking an equilibrium solution, the asymptotically small activator diffusivity implies that it will concentrate in \(O(\varepsilon)\) neighbourhoods centred at a finite collection of points in \(\Omega\). Assuming that \(u \sim O(u_{\text{inner}})\) in each of these neighbourhoods and integrating the activator and inhibitor equations, we obtain

\[
(B - A) \sim \varepsilon O(u_{\text{inner}}) + \varepsilon O(v^{-1})O(u_{\text{inner}}^2), \quad O(v) \sim \varepsilon O(u_{\text{inner}}^2),
\]

respectively, which motivates the rescaling \(u = \varepsilon^{-1} \tilde{u}\) and \(v = \varepsilon^{-1} \tilde{v}\). Substituting this into (1.1a) and dropping the tildes give

\[
\begin{align*}
  u_t & = \varepsilon^2 u_{xx} - u + u^2v^{-1}, & 0 < x < 1, \quad (1.2a) \\
  \tau v_t & = Dv_{xx} - v + \varepsilon^{-1} u^2, & 0 < x < 1, \quad (1.2b)
\end{align*}
\]

and for which we observe both \(u\) and \(v\) will be \(O(1)\) in each interval where \(u\) is concentrated. The appropriate boundary conditions are then

\[
\begin{align*}
  \begin{cases}
    -\varepsilon u_x = A, & -Dv_x = 0, \quad x = 0, \\
    \varepsilon u_x = B, & Dv_x = 0, \quad x = 1.
  \end{cases} \quad (1.2c)
\end{align*}
\]

We remark that the prescription of inhomogeneous Neumann boundary conditions at the endpoints necessitates the formation and persistence of boundary layers for the slowly diffusing activator. In particular, when either \(A > 0\) or \(B > 0\) in (1.2c), the steady-state solutions of 1.2 are not spatially homogeneous and conventional Turing stability analysis is therefore inapplicable. Alternative methods must therefore be used to construct spatially heterogeneous steady states and study their stability. Using
Fig. 1  a Examples of shifted one-spike solution concentrated at $x = 0$ for various values of $A \geq 0$ and with $\varepsilon = 0.05$ and $D = 5$. b Evolution of solution to GM problem with $D = 0.6$, $\varepsilon = 0.005$, $\tau = 0.1$, and $A = B = 0.08$. The initial condition is an unstable two-spike equilibrium where both spikes concentrate at the boundaries. A competition instability predicted by our asymptotic results in Fig. 5a is triggered and leads to the solution settling at an asymmetric pattern.

In Example 1 we assume that $A > 0$ and $B = 0$ and consider the dynamics of a one-spike solution concentrating at $x = 0$. We find that increasing $A > 0$ improves the stability of the single spike solution with respect to Hopf bifurcations. Moreover, numerical simulations indicate that such Hopf bifurcations lead to persistent nonlinear oscillations when $A > 0$ in contrast to when $A = 0$ for which such instabilities lead to the collapse of the single spike solution. In Example 2 we assume $A = B > 0$ and consider a two-spike solution with spikes concentrating at $x = 0$ and $x = 1$. Interestingly, we find that for all $D > 0$ there is a threshold for $A > 0$ below which symmetric two-spike solutions are unstable and for which (1.2) admits a stable asymmetric two-spike solution. Such an asymmetric solution replaces stable one-spike solutions which are no longer viable due to the necessary boundary layers that must form to satisfy the inhomogeneous Neumann boundary conditions. In Fig. 1b we illustrate the dynamics of an unstable symmetric two-spike solution as it undergoes a competition instability and transitions to a stable asymmetric equilibrium. We highlight that the introduction
of symmetric boundary conditions can thus lead to stable asymmetric patterns which is a phenomenon that has only been observed for the GM model in the presence of a precursor gradient (Kolokolnikov et al. 2020). Finally, in Examples 3 and 4 we assume $A > 0$ and $B = 0$ for which we consider the dynamics of two-spike solution in which a spike concentrating at $x = 0$ interacts with either a spike concentrating at $x = 1$ (Example 3) or in the interior $0 < x < 1$ (Example 4). In both examples we observe that there is a limited range of inhibitor diffusivities for which a larger spike concentrates at $x = 0$. Moreover, as in Example 2 we observe that for all $D > 0$ and $A > 0$ below a threshold there is a linearly stable asymmetric two-spike solution in which the spike at $x = 0$ is smaller than the spike at $x = 1$ or in the interior. In each of these examples, we obtain detailed stability thresholds and perform numerical simulations to both illustrate and validate our stability predictions.

The remainder of this paper is organized as follows. In Sect. 2 we use the method of matched asymptotic expansions to construct multi-spike equilibrium solutions. In Sect. 3 we derive a nonlocal eigenvalue problem which determines the linear stability of the multi-spike solutions on an $O(1)$ timescale. Then, in Sect. 4 we rigorously prove partial stability results for an equilibrium consisting of a single boundary spike. In Sect. 5 we consider four examples for which we construct one- and two-spike equilibrium patterns and study their linear stability and dynamics. Finally, in Sect. 6 we conclude with a summary of our results and highlight several open problems and suggestions for future research.

2 Quasi-equilibrium Multi-spike Solutions and Their Slow Dynamics

In this section, we use the method of matched asymptotic expansions to derive an algebraic system and an ordinary differential equation that determine the profile and slow dynamics of a multi-spike quasi-equilibrium solution to (1.2). The derivation uses techniques that are now common in the study of localized patterns in one dimension. Our presentation will therefore be brief, highlighting only the novel aspects introduced by the inhomogeneous Neumann boundary conditions for the activator. We begin by supposing that there are two spikes concentrated at the boundaries $x_L = 0$ and $x_R = 1$ as well as $N$ spikes concentrated in the interior at $0 < x_1 < \cdots < x_N < 1$. In addition, we assume that the spikes are well separated in the sense that $|x_i - x_j| = O(1)$ as $\epsilon \rightarrow 0^+$ for all $i \neq j \in \{L, 1, \ldots, N, R\}$. This last assumption is key for effectively applying the method of matched asymptotic expansions.

We first construct an asymptotic approximation for the solution near $x = 0$ by letting $x = \epsilon y$ where $y = O(1)$ and expanding

$$u \sim u_{L,0}(y) + O(\epsilon), \quad v \sim v_{L,0}(y) + \epsilon v_{L,1}(y) + O(\epsilon^2). \quad (2.1)$$

It is easy to see that $v_{L,0} = \xi_L$ where $\xi_L$ is an undetermined constant, and $u_{L,0}(y) = \xi_L w_c(y + y_L)$ where $w_c(y)$ is the unique homoclinic solution to

$$w''_c - w_c + w_c^2 = 0, \quad 0 < y < \infty, \quad w'_c(0) = 0, \quad w_c(y) \rightarrow 0 \text{ as } y \rightarrow \infty, \quad (2.2a)$$
given explicitly by

\[ w_c(y) = \frac{3}{2} \text{sech}^2 \frac{y}{2}. \]  

(2.2b)

Moreover, the undetermined shift parameter \( y_L \) is chosen to satisfy the inhomogeneous Neumann boundary condition

\[ w'_c(y_L) = -A/\xi_L. \]  

(2.3)

The unknown constants \( \xi_L \) and \( y_L \) are found by matching with the outer solution. To determine the appropriate Neumann boundary conditions for the outer problem, we must first calculate \( v'_{L,1}(y) \) as \( y \to \infty \). This is done by integrating the \( O(\varepsilon) \) equation

\[ Dv''_{L,1} = -\xi^2_L w_c(y + y_L)^2, \quad 0 < y < \infty; \quad v'_{L,1}(0) = 0. \]  

(2.4)

over \( 0 < y < \infty \) to obtain the limit

\[ \lim_{y \to +\infty} v'_{L,1}(y) = -\frac{\xi^2_L}{D} \eta(y_L), \]  

(2.5)

where

\[ \eta(y_0) = \int_0^\infty w_c(y + y_0)^2 dy = \frac{6e^{-2y_0}(3 + e^{-y_0})}{(1 + e^{-y_0})^3}. \]  

(2.6)

Note that \( \eta(0) = 3 \) and \( \eta \to 0^+ \) monotonically as \( z \to \infty \). In a similar way, we obtain the inner solution near \( x = 1 \) by letting \( x = 1 - \varepsilon y \) and finding that

\[ u \sim \xi_R w_c(y + y_R) + O(\varepsilon), \quad v \sim \xi_R + \varepsilon v_{R,1}(y) + O(\varepsilon^2), \]  

where \( y_R \) is determined by solving

\[ w'_c(y_R) = -B/\xi_R, \]  

(2.7)

and for which we calculate the limit

\[ \lim_{y \to +\infty} v'_{R,1}(y) = -\frac{\xi^2_R}{D} \eta(y_R). \]  

(2.8)

We now consider the inner solution at each interior spike location. By balancing dominant terms in a higher-order asymptotic expansion, it can be shown that the interior spike locations vary on an \( O(\varepsilon^{-2}) \) timescale. Therefore, we let \( x_i = x_i(\varepsilon^2 t) \) for each \( i = 1, \ldots, N \) and with \( x = x_i(\varepsilon^2 t) + y \) we calculate the inner asymptotic expansions

\[ u \sim \xi_i w_c(y) + O(\varepsilon), \quad v \sim \xi_i + \varepsilon v_{i,1}(y) + O(\varepsilon^2), \quad i = 1, \ldots, N. \]  

(2.9)
Furthermore, we must impose a solvability condition on the $v_{i1}$ problem which gives

$$\frac{1}{\varepsilon^2} \frac{dx_i}{dt} = -\frac{1}{\xi_i} \left( \lim_{y \to +\infty} v'_{i1}(y) + \lim_{y \to -\infty} v'_{i1}(y) \right).$$  \hspace{1cm} (2.10)

To determine the $2(N+2)$ undetermined constants $\xi_i$ and $y_i$ where $i \in \{L, 1, \ldots, N, R\}$, we must now calculate the outer solution, defined for $|x-x_i| = O(1)$ for each boundary and interior spike location, and match it with each of the inner solutions. Since $w_c$ decays to zero exponentially as $y \to \pm \infty$, we determine that the activator is asymptotically small in the outer region. On the other hand, (2.5) and (2.8) imply the boundary conditions

$$v_x(0) \sim -\frac{\xi_L^2}{D} \eta(y_L), \quad v_x(1) \sim \frac{\xi_R^2}{D} \eta(y_R),$$

while the exponential decay of $w_c$ implies that the following limits hold (in the sense of distributions)

$$\varepsilon^{-1} u^2 \rightarrow \sum_{j=1}^{N} \xi_j^2 \delta(x-x_j), \quad (\varepsilon \to 0^+).$$

Thus, to leading order in $\varepsilon \ll 1$, the outer problem for the inhibitor is given by

$$Dv_{xx} - v = -6 \sum_{j=1}^{N} \xi_j^2 \delta(x-x_j), \quad 0 < x < 1,$$  \hspace{1cm} (2.11)

$$Dv_x(0) = -\xi_0^2 \eta(y_L), \quad Dv_x(1) = \xi_{N+1}^2 \eta(y_R).$$  \hspace{1cm} (2.12)

This boundary value problem can be solved explicitly by letting $G_\omega$ to be the Green’s function satisfying

$$G_{\omega,xx} - \omega^2 G_\omega = -\delta(x-\xi), \quad 0 < x, \xi < 1; \quad G_{\omega,x}(0, \xi) = 0, \quad G_{\omega,x}(1, \xi) = 0,$$

and given explicitly by

$$G_\omega(x, \xi) = \frac{1}{\omega \sinh \omega} \begin{cases} \cosh \omega x \cosh \omega (1-\xi), & 0 < x < \xi, \\ \cosh \omega (1-x) \cosh \omega \xi, & \xi < x < 1. \end{cases}$$  \hspace{1cm} (2.13a)

Formally substituting $\xi = 0$ or $\xi = 1$ into the above expression gives

$$G_\omega(x, 0) = \frac{\cosh \omega (1-x)}{\omega \sinh \omega}, \quad G_\omega(x, 1) = \frac{\cosh \omega x}{\omega \sinh \omega},$$  \hspace{1cm} (2.13c)

which is readily seen to satisfy

$$G_{\omega,xx} - \omega^2 G_\omega = 0, \quad 0 < x < 1,$$
with boundary conditions

\[ G_{\omega,x}(0,0) = -1, \quad G_{\omega,x}(1,0) = 0, \quad G_{\omega,x}(0,1) = 0, \quad G_{\omega,x}(1,1) = 1. \]

Letting \( \omega_0 \equiv D^{-1/2} \), we obtain the following leading order asymptotic expansion for the quasi-equilibrium solution to (1.2)

\[ u_e(x) \sim \xi_L w_c\left(\frac{x}{\varepsilon} + y_L\right) + \xi_R w_c\left(\frac{1-x}{\varepsilon} + y_R\right) + \sum_{j=1}^{N} \xi_j w_c\left(\frac{x-x_j}{\varepsilon}\right). \]  

(2.14a)

\[ v_e(x) \sim \omega_0^2 \left( \xi_L^2 \eta(y_L) G_{\omega_0}(x,0) + \xi_R^2 \eta(y_R) G_{\omega_0}(x,1) + 6 \sum_{j=1}^{N} \xi_j^2 G_{\omega_0}(x,x_j) \right). \]  

(2.14b)

Furthermore, by imposing the consistency condition \( v_e(x_i) = \xi_i \) for each \( i \in \{L, 1, \ldots, N, R\} \) we obtain the system of \( N + 2 \) nonlinear equations

\[ B \equiv \xi - \omega_0^2 \mathcal{G}_{\omega_0} \mathcal{N} \xi^2 = 0, \]  

(2.15a)

where \( \mathcal{G}_{\omega_0} \) and \( \mathcal{N} \) are the \((N+2) \times (N+2)\) matrices given by

\[ (\mathcal{G}_{\omega_0})_{ij} = G_{\omega_0}(x_i,x_j), \quad i, j = L, R, 1, \ldots, N, \quad \mathcal{N} \equiv \text{diag}(\eta(y_L), \eta(y_R), 6, \ldots, 6), \]  

(2.15b)

and

\[ \xi \equiv (\xi_L, \xi_R, \xi_1, \ldots, \xi_N)^T, \quad \xi^2 = (\xi_L^2, \xi_R^2, \xi_1^2, \ldots, \xi_N^2)^T. \]  

(2.15c)

Thus, for given spike configuration \( 0 < x_1 < \cdots < x_N < 1 \), the system (2.15a) together with (2.3) and (2.7) can be solved for the unknown spike heights \( \xi_L, \xi_1, \ldots, \xi_N, \xi_R \) and boundary shifts \( y_L \) and \( y_R \). Summarizing, we have the following proposition.

**Proposition 2.1** In the limit \( \varepsilon \to 0^+ \) and for \( t \ll \mathcal{O}(\varepsilon^{-2}) \), an \( N + 2 \) spike quasi-equilibrium solution to (1.2) consisting of two boundary spikes and \( N \) well-separated interior spikes concentrated at specified locations \( 0 < x_1 < \cdots < x_N < 1 \) is given asymptotically by (2.14) where \( G_{\omega_0}(x, \xi) \) is given explicitly by (2.13b) and \( \omega_0 = D^{-1/2} \). The boundary shifts, \( y_L \) and \( y_R \), and spike heights, \( \xi_L, \xi_1, \ldots, \xi_N, \xi_R \), are found by solving the system of \( N + 4 \) Eqs. (2.3), (2.7), and (2.15a).

The asymptotic solution constructed in the above proposition will not generally be an equilibrium of (1.2) due to the slow, \( \mathcal{O}(\varepsilon^{-2}) \), drift motion of the interior spikes described by (2.10). However, this solution can be made into an equilibrium by choosing the interior spike locations \( x_1, \ldots, x_N \) appropriately.

**Proposition 2.2** The interior spike locations of a multi-spike pattern consisting of two boundary spikes and \( N \) interior spikes vary on an \( \mathcal{O}(\varepsilon^{-2}) \) timescale according to the
differential equation

\[
\frac{1}{\varepsilon^2} \frac{dx_i}{dt} = -\frac{6\xi_i}{D} (\partial_x G_{\omega_0}(x, x_i))_{x=x_i} - \frac{12}{\xi_i D} \sum_{j \neq i} \xi_j^2 G_x(x_j, x_i) - \frac{2}{\xi_i D} \sum_{j \neq i} \left[ \xi_j^2 \eta(y_R) G_x(x_j, 0) + \xi_j^2 \eta(y_R) G_x(x_j, 1) \right], \quad (i = 1, \ldots, N),
\]

where

\[
\{f(x)\}_{x_0} = \lim_{x \to x_0^+} f(x) + \lim_{x \to x_0^-} f(x),
\]

which is to be solved together with (2.15a), (2.3, and (2.7) for the spike heights \(\xi_L, \xi_1, \ldots, \xi_N, \xi_R\) and shifts \(y_L\) and \(y_R\). In particular, if the configuration \(x_1, \ldots, x_N\) is stationary with respect to the ODE (2.16), then to leading order the quasi-equilibrium solution of Proposition 2.1 is an equilibrium for all \(t \geq 0\).

2.1 Equilibrium Multi-spike Solutions by the Gluing Method

We now use an alternative method for constructing asymmetric multi-spike equilibrium solutions to (1.2). This method extends that of Ward and Wei (2002) to account for inhomogeneous Neumann boundary conditions. The key idea is to construct a single-boundary-spike solution in an interval of variable length and use this solution to glue together a multi-spike solution. In particular, we begin considering the problem

\[
\varepsilon^2 u_{xx} - u + v^{-1} u^2 = 0, \quad Dv_{xx} - v + \varepsilon^{-1} u^2 = 0, \quad 0 < x < l,
\]

\[
\epsilon u_x(0) = -A, \quad \epsilon u_x(l) = 0, \quad Dv_x(0) = 0, \quad Dv_x(l) = 0,
\]

where \(l > 0\) is fixed and for which we will use the method of matched asymptotic expansions to construct a single spike solution concentrated at \(x = 0\). Proceeding as in Sect. 2, we readily find that the equilibrium solution in the outer region (i.e. for \(x = O(1)\)) is given by

\[
u(x; l, A) \sim \xi_0 w_c\left(\frac{1}{\xi_0} x + y_0\right), \quad v(x; l, A) \sim \xi_0 \frac{\cosh \omega_0 (l - x)}{\cosh \omega_0 l},
\]

where \(\omega_0 \equiv D^{-1/2}\) while the shift parameter \(y_0\) and spike height \(\xi_0\) satisfy

\[
w'_c(y_0) = -\frac{A}{\xi_0},
\]

and for which, using (2.2b) and (2.6), we explicitly calculate

\[
\xi_0 = \frac{\tanh \omega_0 l}{\omega_0 \eta(y_0)}, \quad y_0 = \log\left(\frac{1 + 3q + \sqrt{9q^2 + 10q + 1}}{2}\right), \quad q \equiv \frac{\omega_0 A}{\tanh \omega_0 l},
\]
for which we remark that $y_0 \sim 4q$ as $q \to 0$ and therefore $\xi_0 \sim (3\omega_0)^{-1} \tanh \omega_0 l$ as $A \to 0^+$. Finally, we note that $y_0$ is monotone increasing in $A$ and monotone decreasing in $D$ and $l$ when $A > 0$ is fixed.

A multi-spike pattern is constructed by first partitioning the unit interval $0 < x < 1$ into $N + 2$ subintervals defined by

$$x_L = 0, \quad x_i = l_L + 2 \sum_{j=1}^{i} l_j + l_i \quad (i = 1, \ldots, N), \quad x_R = 1,$$

$$I_L = [0, l_L), \quad I_i = [x_i - l_i, x_i + l_i) \quad (i = 1, \ldots, N), \quad I_R = [1 - l_R, 1],$$

where $l_L, l_1, \ldots, l_N, l_R$ are chosen to satisfy the $N + 2$ constraints

$$l_L + 2l_1 + \cdots + 2l_N + l_R = 1. \quad (2.22a)$$

$$v(l_L; l_L, A) = v(l_1; l_1, 0) = \cdots = v(l_N; l_N, 0) = v(l_R; l_R, B). \quad (2.22b)$$

The first constraint guarantees that the intervals are mutually disjoint, while the second set of $N + 1$ constraints guarantees the continuity of the multi-spike equilibrium solution

$$u_e(x) = \begin{cases} u(x; l_L, A), & x \in I_L \\ u(|x - x_i|; l_i, 0), & x \in I_i \\ u(1 - x, l_R, B), & x \in I_R \end{cases}, \quad v_e(x) = \begin{cases} v(x; l_L, A), & x \in I_L \\ v(|x - x_i|; l_i, 0), & x \in I_i \\ v(1 - x, l_R, B), & x \in I_R \end{cases}. \quad (2.22c)$$

We remark that the local symmetry of each interior spike implies that the interior spikes are stationary with respect to the slow dynamics found in (2.10), and therefore, the multi-spike solution constructed above is an equilibrium of (1.2).

### 3 Linear Stability of Multi-spike Pattern

In this section, we derive a nonlocal eigenvalue problem (NLEP) that, to leading order in $\varepsilon \ll 1$, determines the linear stability of the quasi-equilibrium solution given in Proposition 2.1 on an $O(1)$ timescale. Letting $u_e$ and $v_e$ be the quasi-equilibrium solution from Proposition 2.1, we consider the perturbations $u = u_e + e^{\lambda t} \Phi$ and $v = v_e + e^{\lambda t} \Psi$ with which (1.2) becomes

$$\varepsilon^2 \Phi_{xx} - \Phi + 2\frac{u_e}{v_e} \Phi - \frac{u_e^2}{v_e^2} \Psi = \lambda \Phi, \quad 0 < x < 1, \quad (3.1a)$$

$$D \Psi_{xx} - \Psi + 2\varepsilon^{-1} u_e \Phi = \tau \lambda \Psi, \quad 0 < x < 1. \quad (3.1b)$$

This problem admits both large and small eigenvalues characterized by $\lambda = O(1)$ and $O(\varepsilon^2)$, respectively. The small eigenvalues are closely related to the linearization of the slow-dynamics (2.16), and the resulting instabilities therefore take place over a $O(\varepsilon^{-2})$ timescale (Wei and Winter 2007). In contrast, the large eigenvalues lead to
amplitude instabilities over a $O(1)$ timescale. In this section, we focus exclusively on
the large eigenvalues and limit our discussion of the small eigenvalues to the specific
example given in Sect. 5.4 in which a two-spike solution consisting of one spike on
the boundary and one interior spike is considered.

Using the method of matched asymptotic expansions as in Sect. 2, we readily find
that, to leading order in $\varepsilon \ll 1$, the inhibitor perturbation $\Psi$ satisfies

$$
D\Psi_{xx} - (1 + \tau \lambda)\Psi = -2 \sum_{j=1}^{N} \xi_j \int_{-\infty}^{\infty} w_c(y)\phi_j(y)dy\delta(x - x_j), \quad 0 < x < 1,
$$

(3.2a)

$$
D\Psi_x(0) = -2\xi_L \int_{0}^{\infty} w_c(y + y_L)\phi_L(y)dy, \quad D\Psi_x(1) = 2\xi_R \int_{0}^{\infty} w_c(y + y_R)\phi_R(y)dy.
$$

(3.2b)

where $\phi_L$ and $\phi_R$ are the leading order inner expansions of the activator perturbation
$\Phi$ at the boundaries satisfying

$$
\mathcal{L}_{y_i} \phi_i - w_c(y + y_i)^2\Psi(x_i) = \lambda \phi_i, \quad 0 < y < \infty, \quad \phi_i'(0) = 0, \quad \phi_i \rightarrow 0 \text{ as } y \rightarrow \infty,
$$

(3.3a)

for $i = L, R$, respectively, while $\phi_1, \ldots, \phi_N$ are the leading order inner expansions
of $\Phi$ at each of the interior spike locations $x_1, \ldots, x_N$ satisfying

$$
\mathcal{L}_0 \phi_i - w_c(y)^2\Psi(x_i) = \lambda \phi_i, \quad -\infty < y < \infty, \quad \phi \rightarrow 0 \text{ as } y \rightarrow \pm \infty,
$$

(3.3b)

for each $i = 1, \ldots, N$, respectively. The linear differential operator $\mathcal{L}_{y_0}$ parametrized
by $y_0 \geq 0$ appearing in each equation is explicitly given by

$$
\mathcal{L}_{y_0} \phi \equiv \phi'' - \phi + 2w_c(y + y_0)\phi.
$$

(3.4)

Since we are interested only in the emergence of instabilities, it suffices to pose (3.3b)
on $y > 0$ with a homogeneous Neumann boundary imposed at $y = 0$. Indeed, for each
$i = 1, \ldots, N$ we may decompose $\phi_i$ into an even and odd component as $\phi_i = \phi_i^{\text{even}} + \phi_i^{\text{odd}}$ from which we readily deduce that the odd component satisfies $\mathcal{L}_0 \phi_i^{\text{odd}} = \lambda \phi_i^{\text{odd}}$
on $y > 0$ with $\phi_i^{\text{odd}} = 0$ at $y = 0$. Since the principal eigenvalue for this problem is
$\lambda = 0$ (corresponding to $\phi_i^{\text{odd}} = w_c'$), we deduce that either $\phi_i^{\text{odd}} = 0$ or else $\lambda \leq 0$.

Therefore, eigenfunctions $\phi_i$, for $i = 1, \ldots, N$, with nontrivial odd components do not
correspond to any unstable eigenvalues of (3.3).

Letting $\omega_i \equiv \sqrt{(1 + \tau \lambda)/D}$ and recalling the definition of $G_{\omega_i}$ in (2.13), we readily
find that the solution to (3.2) is explicitly given by

$$
\Psi(x) = 2\omega_0^2 \sum_{j=L,R,1}^{N} \hat{\xi}_j G_{\omega_j}(x, x_j) \int_{0}^{\infty} w_c(y + y_j)\phi_j(y)dy.
$$

where we let

$$
y_1 = \cdots = y_N = 0, \quad \hat{\xi}_i \equiv \left\{ \begin{array}{ll}
\xi_i, & i = L, R, \\
2\xi_i, & i = 1, \ldots, N.
\end{array} \right.
$$

(3.5)
Evaluating $\Psi(x)$ at each $x = x_i$ and substituting into (3.3) yield the system of NLEPs

$$\mathcal{L}_{y_i} \phi_i - 2\omega_0^2 w_c(y + y_i)^2 \sum_{j=L,R,1}^N \xi_j G_{aw}(x_i, x_j) \int_0^\infty w_c(y + y_j) \phi_j(y) \, dy = \lambda \phi_i, \quad y > 0$$

(3.6a)

$$\phi_i'(0) = 0, \quad \phi_i \to 0 \quad \text{as } y \to +\infty.$$  

(3.6b)

for each $i = L, R, 1, \ldots, N$ where $\mathcal{L}_{y_i}$ is defined by (3.4).

The NLEP system (3.6a) has two key features that distinguish it from analogous NLEPs in singularly perturbed reaction–diffusion systems (Iron et al. 2001; Ward and Wei 2002; Wei 1999; Wei and Winter 2007) and are explored in the rigorous stability results of Sect. 4 as well as in the specific examples of Sect. 5. First, it considers both boundary-bound and interior-bound spikes. As explored in Examples 2 to 4, this has immediate consequences for both the existence and stability of asymmetric patterns even in the zero-flux case where $A = B = 0$. The second distinguishing feature of (3.6a) is the introduction of the shift parameters $y_L \geq 0$ and $y_R \geq 0$. We remark that an analogous negative shift parameter has been examined in the context of near-boundary spike solutions for homogeneous Robin boundary conditions (Berestycki and Wei 2003; Maini et al. 2007). However, as highlighted in the stability results of Sect. 4, the positive shift parameter plays a key role in the stability properties of boundary-bound spikes. An important critical value of the shift parameter is the unique value $y_{0c} > 0$ such that $w''_c(y_{0c}) = 0$ and which is explicitly given by

$$y_{0c} = \log(2 + \sqrt{3}).$$  

(3.7)

In particular, it can be shown that if $y_0 \leq y_{0c}$ then $\mathcal{L}_{y_0}$ has an unstable and stable spectrum, respectively (see Lemma 4.1 below). Moreover, the operator $\mathcal{L}_{y_{0c}}$ has a one-dimensional kernel spanned by $w''_c(y + y_{0c})$.

### 3.1 Reduction of NLEP to an Algebraic System

It is particularly useful to rewrite (3.6a) as an algebraic system as follows. Assuming that $\lambda$ is not an eigenvalue of $\mathcal{L}_{y_i}$ for all $i = L, R, 1, \ldots, N$, we let

$$\phi_i = c_i(\mathcal{L}_{y_i} - \lambda)^{-1} w_c(y + y_i)^2, \quad i \in \{L, R, 1, \ldots, N\},$$

(3.8)

where the coefficients $c_L, c_R, c_1, \ldots, c_N$ are undetermined. Note that in (3.8) the homogeneous Neumann boundary condition $\phi_i'(0) = 0$ is assumed. In addition, note that if $\lambda = 0$ then (3.8) is only valid if $y_L, y_R \neq y_{0c}$.

Substituting into (3.6a) then yields the linear homogeneous system for $c \equiv (c_L, c_R, c_1, \ldots, c_N)^T$

$$\mathcal{J}_{aw} \mathcal{D}_\lambda c = (2\omega_0^2)^{-1} c,$$

(3.9)
where $G_{\omega_0}$ is the $(N + 2) \times (N + 2)$ matrix with entries

$$(G_{\omega_0})_{ij} = G_{\omega_0}(x_i, x_j), \quad (i, j = L, R, 1, \ldots, N), \quad (3.10)$$

while $D_\lambda$ is the diagonal $(N + 2) \times (N + 2)$ matrix given by

$$(D_\lambda)_{ij} = \begin{cases} \frac{1}{\omega_0} \eta(y_i) \xi_i \mathcal{F}_{\gamma y}(\lambda), & i = j = L, R, \\ 6\xi_i \mathcal{F}_0(\lambda), & i = j = 1, \ldots, N, \\ 0, & i \neq j, \end{cases} \quad (3.11)$$

where

$$\mathcal{F}_{\gamma y}(\lambda) = \frac{\int_0^\infty w_c(y + y_0)(\mathcal{L} - \lambda)^{-1} w_c(y + y_0)^2 dy}{\int_0^\infty w_c(y + y_0)^2 dy}, \quad (3.12)$$

and for which (4.3) and (4.4) below imply that for all $y_0 \neq y_0 c$

$$\mathcal{F}_{\gamma y}(0) = 1 + \frac{w_c'(y_0)w_c(y_0)^2}{2w_c''(y_0)\eta(y_0)}. \quad (3.13)$$

Comparing (3.9) and (3.6), it follows that $\lambda$ is an eigenvalue of (3.6) if and only if $(2\omega_0^2)^{-1}$ is an eigenvalue of $G_{\omega_0} D_\lambda$. In particular, when $\lambda$ is not an eigenvalue of $\mathcal{L}_L$, $\mathcal{L}_R$, and $\mathcal{L}_0$, then it is an eigenvalue of the NLEP (3.6) if and only if it satisfies the algebraic equation

$$\det(\mathbb{I}_{N + 2} - 2\omega_0^2 G_{\omega_0} D_\lambda) = 0, \quad (3.14)$$

where $\mathbb{I}_{N + 2}$ is the $(N + 2) \times (N + 2)$ identity matrix.

We conclude by noting that if either $y_L = y_0 c$ and/or $y_R = y_0 c$ then the algebraic reduction fails when searching for a zero eigenvalue $\lambda = 0$ since $\mathcal{L}_{y_0 c}$ is not invertible. However, in this case we can deduce an analogous system. In particular, letting $\lambda = 0$ and assuming that $y_L = y_0 c$ and $y_R \neq y_0 c$, we multiply the $i = L$ NLEP in (3.6) by $w_c'(y + y_0 c)$ and integrate over $0 < y < \infty$ to get

$$\xi_L \int_0^\infty w_c(y + y_L) \phi_L dy = -\frac{1}{G_{\omega_0}(0, 0)} \sum_{j=R,1}^N \xi_j G_{\omega_0}(0, x_j) \int_0^\infty w_c(y + y_j) \phi_j dy. \quad (3.15)$$

Proceeding as above, we then deduce that the NLEP (3.6) with $\lambda = 0$ is then equivalent to the algebraic equation

$$\det(\mathbb{I}_{N + 1} - 2\omega_0^2 \tilde{G}_{\omega_0} \mathcal{D}) = 0, \quad (3.16)$$

where $\tilde{G}_{\omega_0}$ and $\mathcal{D}$ are the $(N + 1) \times (N + 1)$ matrices with entries

$$(\tilde{G}_{\omega_0})_{ij} = \phi_{ij} - \frac{1}{G_{\omega_0}(0, 0)} G_{\omega_0}(x_i, 0) G_{\omega_0}(0, x_j), \quad (\mathcal{D})_{ij} = D_{ij}, \quad (i, j = R, 1, \ldots, N). \quad (3.17)$$

The same approach can likewise be used if $y_L = y_R = y_0 c$. \hfill $\Box$
3.2 Zero Eigenvalues of the NLEP and the Consistency Condition

The conditions under which $\lambda = 0$ is an eigenvalue of the NLEP (3.6a) can be directly linked to the system (2.15a) as highlighted in Wei and Winter (2007). Specifically, assume that $x_1, \ldots, x_N$ are fixed (not necessarily at an equilibrium configuration of the slow dynamics ODE (2.16)) and let $\xi_L, \xi_R, \xi_1, \ldots, \xi_N$ together with $y_L$ and $y_R$ solve (2.15a), (2.3, and (2.7) with the additional assumption that $y_L, y_R \neq y_0$. From the definition of $\eta$ in (2.6) and from (2.3) and (2.7), we calculate

$$\frac{\partial \eta(y_i)}{\partial \xi_i} = w_c(y_i)^2 \frac{w_c'(y_i)}{\xi_i w_c''(y_i)},$$

for $i = L, R$. Taking the Jacobian of the quasi-equilibrium system (2.15a) and recalling the definition of $D_\lambda$ given in (3.11), we deduce that

$$\nabla_\xi B = I - 2 \omega_0^2 D_\lambda w_0 D_0,$$

where $B$ is defined in (2.15a). Together with the discussion of Sect. 3.1, we deduce that if $y_L, y_R \neq 0$ and each $x_1, \ldots, x_N$ is independent of $\xi_L, \xi_R, \xi_1, \ldots, \xi_N$, then $\lambda = 0$ is an eigenvalue of the NLEP (3.6a) if and only if the Jacobian $\nabla_\xi B$ is singular.

4 Rigorous Stability and Instability Results for the Shifted NLEP

In this section, we rigorously prove instability and stability results for the shifted NLEP

$$\mathcal{L}_{y_0} \phi - \mu \int_0^\infty w \phi dy \int_0^\infty w^2 dy = \lambda \phi, \quad 0 < y < \infty; \quad \phi'(0) = 0; \quad \phi \to 0 \text{ as } y \to \infty,$$

where $\mu$ is a real constant and for a fixed value of $y_0 \geq 0$ we define

$$\mathcal{L}_{y_0} \phi \equiv \phi'' - \phi + 2 w \phi, \quad w(y) \equiv w_c(y + y_0),$$

and where $w_c$ is the unique solution to (2.2a). When $y_0 = 0$ the NLEP (4.1) is stable if $\mu > 1$ and unstable if $\mu < 1$ (Wei 1999). We begin by collecting a few facts about the operator $\mathcal{L}_{y_0}$ and its spectrum. First, we calculate

$$\mathcal{L}_{y_0}^{-1} w^2 = w - \frac{w'(0)}{w''(0)} w', \quad \mathcal{L}_{y_0}^{-1} w = w + \frac{1}{2} y w' - \frac{3 w'(0)}{2 w''(0)} w'$$

$\square$ Springer
where the additional terms are chosen so that homogeneous Neumann boundary conditions at \( y = 0 \) are satisfied and which we use to compute

\[
\int_0^\infty w \mathcal{L}^{-1} w^2 \, dy = \int_0^\infty w^2 \, dy + \frac{w'(0) w(0)^2}{2 w''(0)}, \quad \int_0^\infty w \mathcal{L}^{-1} w \, dy
\]

\[
= \frac{3}{4} \int_0^\infty w^2 \, dy + \frac{3 w'(0) w(0)^2}{4 w''(0)}, \quad (4.4a)
\]

\[
\int_0^\infty w^2 \mathcal{L}^{-1} w^2 \, dy = \int_0^\infty w^3 \, dy + \frac{w'(0) w(0)^3}{3 w''(0)}, \quad \int_0^\infty w^3 \, dy
\]

\[
= \frac{6}{5} \int_0^\infty w^2 \, dy + \frac{3 w(0) w'(0)}{5}. \quad (4.4b)
\]

In the next two lemmas, we describe some key properties of the eigenvalue problem

\[
\mathcal{L} \Phi = \Lambda \Phi, \quad 0 < y < \infty; \quad \Phi'(0) = 0; \quad \Phi \to 0, \quad \text{as} \quad y \to +\infty. \quad (4.5)
\]

**Lemma 4.1** Let \( \gamma_0 \geq 0 \) and let \( \Lambda_0 \) be the principal eigenvalue of (4.5). Then, \( \Lambda_0 = 0 \) if \( \gamma_0 = \gamma_0^c \) and \( \Lambda_0 \leq 0 \) if \( \gamma_0 \geq \gamma_0^c \). Furthermore, the eigenfunction corresponding to the principal eigenvalue is of one sign.

**Proof** Since \( \mathcal{L} \) is self-adjoint, the variational characterization

\[
- \Lambda_0 = \inf_{\Phi \in H^2((0, \infty))} \frac{\int_0^\infty (|\Phi'|^2 + |\Phi|^2 - 2w|\Phi|^2) \, dy}{\int_0^\infty |\Phi|^2 \, dy}, \quad (4.6)
\]

implies that the principal eigenfunction \( \Phi_0 \) is of one sign. Since \( \Phi_0(0) \neq 0 \), we may, without loss of generality, assume that \( \Phi_0(0) = 1 \) and \( \Phi_0 > 0 \). Now we multiply (4.5) by \( w' \) and integrate by parts to get

\[
\Lambda_0 = \frac{w''(0)}{\int_0^\infty w' \Phi_0 \, dy}, \quad (4.7)
\]

where we remark that the denominator is negative since \( w' \leq 0 \) for all \( y \geq 0 \). The claim follows by noting that \( w''(0) = 0 \) when \( \gamma_0 = \gamma_0^c \) and \( w''(0) \geq 0 \) for \( \gamma_0 \geq \gamma_0^c \). \( \square \)

**Lemma 4.2** Let \( \Lambda_1 \) be the second eigenvalue of \( \mathcal{L} \). Then, \( \Lambda_1 < 0 \) for all \( \gamma_0 \geq 0 \).

**Proof** First, note that the second eigenfunction \( \Phi_1 \) must cross zero at least once since

\[
\int_0^\infty \Phi_0 \Phi_1 \, dy = 0 \quad \text{and} \quad \Phi_0 \text{ is of one sign}.
\]

Next, we assume toward a contradiction that \( \Lambda_1 \geq 0 \). We begin by showing that \( \Phi_1 \) has exactly one zero in \( 0 < y < \infty \). Assume that \( \Phi_1 \) has more than one zero and choose \( 0 < a < b < \infty \) such that \( \Phi_1(a) = \Phi_1(b) = 0 \) and \( \Phi_1 > 0 \) in \( a < y < b \). Then, \( \Phi_1'(a) > 0 \) and \( \Phi_1'(b) < 0 \) so
we obtain the contradiction

\[ 0 \geq \Lambda_1 \int_a^b w' \Phi_1 \, dy = \int_a^b \left( w' \mathcal{L}_{y_0} \Phi_1 \right) \, dy = w'(b) \Phi_1(b) - w'(a) \Phi_1(a) > 0, \]  

(4.8)

where we have used \( \mathcal{L}_{y_0} w' = 0 \) and \( w'(y) = w'_c(y + y_0) < 0 \) for all \( y > 0 \). Thus, \( \Phi_1 \) has a unique zero \( 0 < a < \infty \) and we may assume that \( \Phi_1 \equiv 0 \) for \( y \approx a \). Setting \( b = \infty \) in (4.8), we get a contradiction. \( \square \)

In Fig. 2a we plot the principal and second eigenvalues of the operator \( \mathcal{L}_{y_0} \) which we calculated numerically (see “Appendix B” for details on the numerical method).

Lemma 4.1 implies that the NLEP will have different stability properties depending on whether \( y_0 \) is greater than or smaller than \( y_{0c} \). We will henceforth refer to \( 0 \leq y_0 < y_{0c} \) and \( y_0 > y_{0c} \) as the small-shift and large-shift cases, respectively. When \( y_0 = 0 \), it is known that for \( \mu > 0 \) sufficiently large, the NLEP (4.1) is stable. In this sense, the nonlocal term appearing in (4.1) can stabilize the spectrum of the linearized operator \( \mathcal{L}_{y_0} \). Since all the eigenvalues of \( \mathcal{L}_{y_0} \) are negative in the large-shift case, we expect the spectrum of the NLEP (4.1) to remain stable for all \( \mu \geq 0 \). Restricting our attention to real eigenvalues, we have the following stability result for the large-shift case.

**Theorem 4.1** All real eigenvalues of the NLEP (4.1) are negative when \( y_0 > y_{0c} \).

To prove this, we first prove the following lemma.

**Lemma 4.3** Let \( y_0 > y_{0c} \) and suppose that \( \phi \) satisfies

\[ \mathcal{L}_{y_0} \phi - \lambda \phi \geq 0, \quad 0 < y < \infty; \quad \phi'(0) \geq 0; \quad \phi \to 0, \quad as \quad y \to +\infty, \]  

(4.9)

where \( \lambda \geq 0 \). Then \( \phi < 0 \) for all \( y \geq 0 \).

**Proof** Assume toward a contradiction that \( \phi > 0 \) in \( 0 \leq a < y < b \leq \infty \). Without loss of generality, we may assume that \( \phi(a) = 0 \) if \( a > 0 \) and \( \phi(0) > 0 \) if \( a = 0 \). Then, for any such \( 0 \leq a < b \leq \infty \) we have

\[ \phi(a) \geq 0, \quad \phi'(a) \geq 0, \quad \phi(b) = 0, \quad \phi'(b) \leq 0. \]  

(4.10)

Let \( g(y) \equiv w''(y) - \beta w'(y) \) where \( \beta \equiv \frac{\max_{y \geq 0} |w''(y)|}{w''(a)} \) is well defined and positive since all the derivatives of \( w \) are bounded and \( w''(y) > 0 \) for all \( y \geq 0 \) when \( y_0 > y_{0c} \). Then, \( g > 0 \) for all \( y \geq 0, \ g'(a) \leq 0, \) and moreover \( (\mathcal{L}_{y_0} - \lambda)g = \mathcal{L}_{y_0} w'' - \lambda g = -(w')^2 - \lambda g < 0 \). Integrating by parts, we obtain the contradiction

\[ 0 < \int_a^b g(\mathcal{L}_{y_0} - \lambda) \phi \, dy - \int_a^b \phi(\mathcal{L}_{y_0} - \lambda)g \, dy \]
\[ = g(b) \phi'(b) - g(a) \phi'(a) - g'(b) \phi(b) + g'(a) \phi(a) \leq 0. \]  

(4.11)

\( \square \)
**Proof [Theorem 4.1]** Suppose that $\lambda \geq 0$ is an eigenvalue of (4.1) so that by Lemma 4.1 the operator $\mathcal{L}_{y_0} - \lambda$ is invertible and from (4.1) we calculate

$$
\phi = \mu \frac{\int_0^\infty w \phi \, dy}{\int_0^\infty w^2 \, dy} (\mathcal{L}_{y_0} - \lambda)^{-1} w^2.
$$

But $w^2 > 0$ so by Lemma 4.3 we obtain the contradiction

$$
1 = \mu \frac{\int_0^\infty w (\mathcal{L}_{y_0} - \lambda)^{-1} w^2 \, dy}{\int_0^\infty w^2 \, dy} < 0.
$$

From Theorem 4.1 we immediately deduce that the NLEP does not admit a zero eigenvalue for any $\mu \geq 0$ when $y_0 > y_{0c}$. On the other hand, when $0 \leq y_0 \leq y_{0c}$ we suspect that the NLEP admits a zero eigenvalue for an appropriate choice of $\mu \geq 0$. When $y_0 = y_{0c}$, this is the case for $\mu = 0$. When $0 \leq y_0 < y_{0c}$, we set $\lambda = 0$ in (4.1) and obtain

$$
\mathcal{L}_{y_0} \phi = \mu \frac{\int_0^\infty w \phi \, dy}{\int_0^\infty w^2 \, dy} w^2.
$$

Using (4.3), we calculate $\phi = \mathcal{L}_{y_0}^{-1} w^2$ and substitute back into (4.13) to deduce that $\lambda = 0$ is an eigenvalue if and only if

$$
\mu = \mu_c(y_0) \equiv \frac{\int_0^\infty w^2 \, dy}{\int_0^\infty w \mathcal{L}_{y_0}^{-1} w^2 \, dy} = \frac{\int_0^\infty w^2 \, dy}{\int_0^\infty w^2 \, dy + \frac{w'(0)w(0)^2}{2w''(0)}}.
$$

Note that $\mu_c(y_0) \leq 0$ if $y_0 \geq y_{0c}$. In terms of the critical value $\mu_c$, we have the following instability result for the small-shift case.

**Theorem 4.2** Let $0 \leq y_0 < y_{0c}$ and $0 \leq \mu < \mu_c$ where critical value $\mu_c$ is defined in (4.14). Then, the NLEP (4.1) admits a positive real eigenvalue.

**Proof** Let $\Lambda_0$ be the principal eigenvalue of $\mathcal{L}_{y_0}$. First, note that by Lemma 4.1 and 4.2 the principal and second eigenvalues of $\mathcal{L}_{y_0}$ satisfy $\Lambda_1 < 0 < \Lambda_0$. Moreover, the corresponding eigenfunction $\Phi_0$ is of one sign and we may assume that $\Phi_0 > 0$ and $\int_0^\infty \Phi_0^2 = 1$. Observe that if $\lambda_0 \neq \Lambda_0$ is a positive eigenvalue of the NLEP (4.1) then

$$
\phi = \mu \frac{\int_0^\infty w \phi \, dy}{\int_0^\infty w^2 \, dy} (\mathcal{L}_{y_0} - \lambda_0)^{-1} w^2,
$$

and since $\int_0^\infty w \phi \, dy \neq 0$ the above equation is equivalent to $h(\lambda_0) = 0$ where

$$
h(\lambda) \equiv \int_0^\infty w (\mathcal{L}_{y_0} - \lambda)^{-1} w^2 \, dy - \frac{\int_0^\infty w^2 \, dy}{\mu}.
$$

We now show that such a $\lambda_0$ can always be found in $0 < \lambda_0 < \Lambda_0$ for $0 \leq \mu < \mu_c$. 

 Springer
First, we calculate \( h(0) = \int_0^\infty w^2(\mu_c^{-1} - \mu^{-1}) \, dy < 0 \). Next, we let \( \psi_\lambda \) be the unique \( \lambda \)-dependent solution to

\[
(\mathcal{L}_{\gamma_0} - \lambda) \psi_\lambda = w^2, \quad 0 < y < \infty; \quad \psi_\lambda'(0) = 0.
\]

Decomposing \( \psi_\lambda = c_0 \Phi_0 + \psi_\lambda^\perp \) where \( \int_0^\infty \Phi_0 \psi_\lambda^\perp \, dy = 0 \), we find that \( \psi_\lambda^\perp \) satisfies

\[
(\mathcal{L}_{\gamma_0} - \lambda) \psi_\lambda^\perp = w^2 - c_0(\Lambda_0 - \lambda) \Phi_0, \quad 0 < y < \infty; \quad (\psi_\lambda^\perp)'(0) = 0. \tag{4.16}
\]

Multiplying by \( \Phi_0 \) and integrating by parts, we obtain \( c_0 = (\Lambda_0 - \lambda)^{-1} \int_0^\infty w^2 \Phi_0 \, dy \) and therefore

\[
h(\lambda) = \int_0^\infty w^2 \Phi_0 \, dy + \int_0^\infty \psi_\lambda^\perp \, dy - \frac{\int_0^\infty w^2 \, dy}{\mu}. \tag{4.17}
\]

On the other hand, if we multiply (4.16) by \( \psi_\lambda^\perp \) and integrate then we obtain

\[
- \int_0^\infty |\psi_\lambda^\perp|^2 \left( \lambda + \frac{-\int_0^\infty \psi_\lambda^\perp \mathcal{L}_{\gamma_0} \psi_\lambda^\perp}{\int_0^\infty |\psi_\lambda^\perp|^2} \right) \, dy = \int_0^\infty w^2 \psi_\lambda^\perp \, dy. \tag{4.18}
\]

By Lemma 4.2 and the variational characterization of the second eigenvalue of \( \mathcal{L}_{\gamma_0} \), we obtain

\[
0 < -\Lambda_1 = \inf_{\Phi \in H^2([0,\infty))} \frac{\int_0^\infty (|\Phi'|^2 + |\Phi|^2 - 2w|\Phi|^2) \, dy}{|\Phi|^2} \leq \frac{-\int_0^\infty \psi_\lambda^\perp \mathcal{L}_{\gamma_0} \psi_\lambda^\perp \, dy}{\int_0^\infty |\psi_\lambda^\perp|^2 \, dy}. \]

Substituting into (4.18), we calculate \( ||\psi_\lambda^\perp||_{L^2([0,\infty))} \leq \lambda^{-1} ||w^2||_{L^2([0,\infty))} ||\psi_\lambda^\perp||_{L^2([0,\infty))} \) so that \( ||\psi_\lambda^\perp||_{L^2([0,\infty))} \) and hence also \( \int_0^\infty w \psi_\lambda^\perp \, dy \) are bounded as \( \lambda \to \Lambda_0 > 0 \). Therefore, from (4.17) we deduce \( h(\lambda) \to +\infty \) as \( \lambda \to \Lambda_0^- \). By a continuity argument, we deduce the existence of a \( \lambda_0 \in (0, \Lambda_1) \) such that \( h(\lambda_0) = 0 \).

We conclude this section by establishing sufficient conditions for the stability of the NLEP (4.1) in both the small- and large-shift cases. Suppose that \( \phi = \phi_R + i\phi_I \) and \( \lambda = \lambda_R + i\lambda_I \) satisfies the NLEP. Separating real and imaginary parts in (4.1) then yields the system

\[
\mathcal{L}_{\gamma_0} \phi_R - \mu \frac{\int_0^\infty w \phi_R \, dy}{\int_0^\infty w^2 \, dy} w^2 = \lambda_R \phi_R - \lambda_I \phi_I, \quad \mathcal{L}_{\gamma_0} \phi_I - \mu \frac{\int_0^\infty w \phi_I \, dy}{\int_0^\infty w^2 \, dy} w^2 = \lambda_R \phi_I + \lambda_I \phi_R. \tag{4.19a}
\]
Multiplying the first and second equations by \( \phi_R \) and \( \phi_I \), respectively, integrating, and then adding them together give

\[
\lambda_R \int_0^\infty |\phi|^2 \, dy = -L_1(\phi_R, \phi_R) - L_1(\phi_I, \phi_I),
\]

where we define

\[
L_1(\Phi, \Phi) \equiv \int_0^\infty (|\Phi'|^2 + \Phi^2 - 2w\Phi^2) \, dy + \mu \int_0^\infty w\Phi \int_0^\infty w^2\Phi \, dy \int_0^\infty w^2 \, dy. \tag{4.21}
\]

It is clear that if \( L_1(\Phi, \Phi) > 0 \) for all \( \Phi \in H^2((0, \infty)) \) then the NLEP (4.1) will be linearly stable. In the next theorem, we determine sufficient conditions on \( \mu \geq 0 \) and \( y_0 \geq 0 \) for which the NLEP is linearly stable.

**Theorem 4.3** Suppose that \( \mu_1(y_0) < \mu < \mu_2(y_0) \) if \( 0 \leq y_0 < y_0c \) and \( 0 \leq \mu < \mu_1(y_0) \) if \( y_0 > y_0c \) where

\[
\mu_1(y_0) = \frac{2 \int_0^\infty w^2 \, dy}{\int_0^\infty w \mathcal{L}^{-1}_{y_0} w \, dy + \sqrt{\int_0^\infty w \mathcal{L}^{-1}_{y_0} w \, dy \int_0^\infty w^2 \mathcal{L}^{-1}_{y_0} w^2 \, dy}}, \tag{4.22}
\]

\[
\mu_2(y_0) = \frac{2 \int_0^\infty w^2 \, dy}{\int_0^\infty w \mathcal{L}^{-1}_{y_0} w \, dy - \sqrt{\int_0^\infty w \mathcal{L}^{-1}_{y_0} w \, dy \int_0^\infty w^2 \mathcal{L}^{-1}_{y_0} w^2 \, dy}}, \tag{4.23}
\]

and where \( \mathcal{L}_{y_0} \) and \( w \) are given by (4.2). Then, \( \text{Re} \lambda < 0 \) for all eigenvalues of the NLEP (4.1).

**Proof** We first prove the result for \( 0 \leq y_0 < y_0c \). When \( \mu = 2 \) and \( y_0 = 0 \), Lemma 5.1 (2) in Wei (1999) implies that \( L_1(\Phi, \Phi) > 0 \) for all \( \Phi \in H^2((0, \infty)) \) and hence, by restricting to even functions, also for all \( \Phi \in H^2((0, \infty)) \). In particular, by the variational characterization of the principal eigenvalue, this implies that the principal eigenvalue of the self-adjoint operator

\[
L_1 \Phi \equiv \mathcal{L}^{-1}_{y_0} \Phi - \frac{\mu}{2} \int_0^\infty w \Phi \, dy \int_0^\infty w^2 \, dy - \frac{\mu}{2} \int_0^\infty w^2 \Phi \, dy \int_0^\infty w^2 \, dy \tag{4.24}
\]

must be negative. We then perturb \( y_0 \geq 0 \) and \( \mu \) until \( L_1 \) has a zero eigenvalue and for which we may solve

\[
\Phi = c_0 \mathcal{L}^{-1}_{y_0} w^2 + c_1 \mathcal{L}^{-1}_{y_0} w. \tag{4.25}
\]

Substituting back into \( L_1 \Phi = 0 \), we obtain the system

\[
\begin{align*}
\left( \frac{\mu}{2} 
\int_0^\infty w \mathcal{L}^{-1}_{y_0} w^2 \, dy - 1 \right) c_0 + \frac{\mu}{2} \int_0^\infty w \mathcal{L}^{-1}_{y_0} w \, dy c_1 &= 0, \tag{4.26} \\
\frac{\mu}{2} \int_0^\infty w^2 \mathcal{L}^{-1}_{y_0} w \, dy c_0 + \left( \frac{\mu}{2} \int_0^\infty w^2 \mathcal{L}^{-1}_{y_0} w \, dy - 1 \right) c_1 &= 0. \tag{4.27}
\end{align*}
\]
Fig. 2  a Plot of the numerically computed principal and second eigenvalues of the operator $L_{y_0}$. The dashed vertical line corresponds to $y_0 = y_{0c}$. b Plot of the stability thresholds $\mu_1$ and $\mu_2$ as functions of $y_0$. The dashed vertical and horizontal lines correspond to $y_0 = y_{0c}$ and $\mu = 2$, respectively. The NLEP (4.1) has been rigorously demonstrated to be stable in the region bounded by the curves $\mu_1$ and $\mu_2$. Note that $\mu_1$ and $\mu_2$ are interchanged as $y_0$ passes through $y_{0c}$. c Plot of $\mu_1(y_0) - \mu_2(y_0)$ for $0 \leq y_0 \leq y_{0c}$. The NLEP is unstable for $\mu < \mu_c$ and stable for $\mu_1 < \mu < \mu_2$ when $0 \leq y_0 < y_{0c}$. It is conjectured that the NLEP is stable for $\mu > \mu_c$.

Since $\int_0^\infty w^2 L_{y_0}^{-1} w \, dy = \int_0^\infty w^2 \, dy$, a nontrivial solutions exists if and only if

$$\left( \frac{\mu}{2} \frac{\int_0^\infty w^2 \, dy}{\int_0^\infty \frac{L_{y_0}^{-1} w^2 \, dy}{w^2 \, dy}} - 1 \right)^2 - \left( \frac{\mu_1}{2} \frac{\int_0^\infty w^2 \, dy}{\int_0^\infty \frac{L_{y_0}^{-1} w^2 \, dy}{w^2 \, dy}} - 1 \right)^2 = 0,$$  

(4.28)

where explicit formulae for each integral can be found in (4.4). When $\mu = 2$ and $y_0 = 0$, the left-hand side of (4.28) equals $-9/10 < 0$ and therefore we have stability for $0 \leq y_0 < y_{0c}$ if

$$\left( \frac{\mu}{2} \frac{\int_0^\infty w^2 \, dy}{\int_0^\infty \frac{L_{y_0}^{-1} w^2 \, dy}{w^2 \, dy}} - 1 \right)^2 - \left( \frac{\mu_1}{2} \frac{\int_0^\infty w^2 \, dy}{\int_0^\infty \frac{L_{y_0}^{-1} w^2 \, dy}{w^2 \, dy}} - 1 \right)^2 < 0,$$  

(4.29)

which is easily seen to be equivalent to $\mu_1 < \mu < \mu_2$.

The thresholds $\mu_1$ and $\mu_2$ are singular as $y_0 \to y_{0c}$ and therefore the continuity argument from above does not extend to $y_0 > y_{0c}$. However, $L_1(\Phi, \Phi) > 0$ by Lemma 4.1 if $y_0 > y_{0c}$ and $\mu = 0$. Therefore, we proceed with the same continuity argument as above, but starting from $\mu = 0$. This yields the same criteria, but since $L_{y_0}^{-1} w^2 < 0$ by Lemma 4.3 the sufficient condition is now $\mu_2(y_0) < 0 \leq \mu < \mu_1(y_0)$.  

Both of the stability thresholds $\mu_1$ and $\mu_2$ defined in (4.22) as well as the instability threshold $\mu_c$, defined in (4.14) are easily computed using (4.4). In Figs. 2b and 2c we plot the stability thresholds and the difference $\mu_1 - \mu_c$, respectively. In particular, from the plot in 2c we see that $\mu_1 > \mu_c$. We conjecture, that as in the $y_0 = 0$ case, the NLEP is stable for all $\mu > \mu_c$. In “Appendix B” we provide numerical support.
for this conjecture by plotting \( \text{Re}\lambda_0 \) versus \( \mu \) and \( y_0 \) in Fig. 12a. In addition, we plot \( \Lambda_0 - \text{Re}(\lambda_0) \) in Fig. 12b which suggest that \( \text{Re}(\lambda_0) \leq \Lambda_0 \).

5 Examples

In this section, we illustrate the effect of introducing a nonzero boundary flux for the activator by considering three distinct examples. Specifically, we first study the stability of a single boundary spike concentrated at \( x = 0 \) when \( A \geq 0 \) and \( B = 0 \). Using a winding number argument, we illustrate that the stability of the single spike is improved by increasing the boundary flux \( A \). Moreover, we illustrate that if \( A \) exceed a threshold, then the spike is stable independently of the parameters \( \tau \geq 0 \) and \( D > 0 \). We then consider the structure and stability of a two-boundary-spike pattern when the boundary fluxes are equal, \( A = B \geq 0 \). One of the key findings is that if \( A > 0 \) then the range of \( D > 0 \) values for which asymmetric patterns exist is extended. Additionally, by assuming that \( \tau \ll 1 \) we study the stability of both symmetric and asymmetric two-boundary-spike patterns to competition (zero eigenvalue crossing) instabilities. We demonstrate that one branch of asymmetric patterns is always stable. Similarly, in our final example we consider a two-boundary-spike pattern with a one-sided boundary flux \( A \geq 0 \) and \( B = 0 \). We demonstrate the existence of several asymmetric patterns, with a certain branch of these patterns always being stable. For each example we include full numerical simulations of the GM system (1.2) using the finite element software FlexPDE (PDE Solutions Inc.).

5.1 Example 1: One Boundary Spike at \( x = 0 \) with \( A > 0 \) and \( B = 0 \)

In this example, we assume that \( B = 0 \) and investigate the role of a non-negative flux, \( A \geq 0 \), on the stability of a single boundary spike concentrated at \( x = 0 \). We denote the left boundary shift parameter by \( y_0 = y_L \) so that using (2.13b) and (2.21) we reduce (3.6a) to (4.1 where

\[
\mu(\lambda) = \frac{2\omega_0 \tanh \omega_0}{\omega_\lambda \tanh \omega_\lambda}.
\]

(5.1)

Recalling that \( \omega_\lambda = \sqrt{(1 + \tau \lambda)/D} \), we first observe that \( 0 < \mu(\lambda) \leq 2 \) for all real-valued \( \lambda \geq 0 \) so that by Theorem 4.3 and Fig. 2b the NLEP has no non-negative real eigenvalues. Next, we determine whether the NLEP has any unstable complex-valued eigenvalues by using a winding number argument. Assuming that \( \lambda \) is not in the spectrum of \( \mathcal{L}_{y_0} \), we let \( \phi = (\mathcal{L}_{y_0} - \lambda)^{-1}w_c(y + y_0)^2 \) so that as in Sect. 3.1 the NLEP reduces to the algebraic equation

\[
\mathcal{A}_{y_0}(\lambda) \equiv \frac{1}{\mu(\lambda)} - \mathcal{F}_{y_0}(\lambda) = 0,
\]

(5.2)

where \( \mathcal{F}_{y_0}(\lambda) \) is defined in (3.12). In Fig. 11 we plot \( \mathcal{F}_{y_0}(0) \) versus \( y_0 \), as well as the real and imaginary parts of \( \mathcal{F}_{y_0}(i\lambda I) \) versus \( \lambda I \) for select values of \( y_0 \). We integrate
in $\lambda$ over a closed counter-clockwise contour consisting of the imaginary axis and a large semicircle in the right half-plane. Since

$$\mathcal{F}_{y_0}(\lambda) = O(|\lambda|^{-1}) \quad \text{and} \quad \mu(\lambda) = O(\lambda^{-1/2}) \quad \text{as} \quad |\lambda| \to \infty, \quad \text{Re}\lambda > 0, \quad (5.3)$$

the change in argument of $\mathcal{A}_{y_0}(\lambda)$ over the large semicircle is $\pi$. Moreover, in $\text{Re}\lambda > 0$, $\mu(\lambda) \neq 0$ whereas by Lemmas 4.1 and 4.2 we deduce that $\mathcal{F}_{y_0}(\lambda)$ has one (resp. zero) pole(s) if $y_0 < y_{0c}$ (resp. $y_0 \geq y_{0c}$). Letting $Z$ denote the number of zeroes of $\mathcal{A}_{y_0}(\lambda)$ in $\text{Re}\lambda > 0$, it follows from the argument principle that

$$Z = \frac{1}{\pi} \Delta \arg \mathcal{A}_{y_0}(i\lambda_I)|_{+\infty}^0 \begin{cases} 
5/4, & y_0 < y_{0c}, \\
1/4, & y_0 \geq y_{0c}, 
\end{cases} \quad (5.4)$$

where the first term on the right-hand side denotes the change in argument of $\mathcal{A}_{y_0}(\lambda)$ as $\lambda$ follows the imaginary axis from $\lambda = +i\infty$ to $\lambda = 0$. Note in addition that we have used $\mathcal{A}_{y_0}(\lambda) = \mathcal{A}_{y_0}(\lambda)$ to obtain $\Delta \arg \mathcal{A}_{y_0}(i\lambda_I)|_{+\infty}^0 = 2\Delta \arg \mathcal{A}_{y_0}(i\lambda_I)|_{+\infty}^0$. From (5.3) we immediately deduce that $\arg \mathcal{A}_{y_0}(+i\infty) = \pi/4$. On the other hand, using (4.4), we evaluate $\mathcal{A}_{y_0}(0) = \frac{1}{2} - \mathcal{F}_{y_0}(0) \leq 0$ for $y_0 \leq y_{0c}$ (see also Fig. 11a). We will consider the cases $y_0 \geq y_{0c}$ and $y_0 < y_{0c}$ separately below.

If $y_0 \geq y_{0c}$, then $\text{Re}\mathcal{F}_{y_0}(i\lambda_I) < 0$ for all $\lambda_I > 0$ (see Fig. 11b) so $\mathcal{A}_{y_0}(i\lambda_I)$ never crosses the imaginary axis for all $\lambda_I > 0$. As a result $\Delta \arg \mathcal{A}_{y_0}(i\lambda_I)|_{+\infty}^0 = -\pi/4$ and therefore $Z = 0$ if $y_0 > y_{0c}$. Since $y_0$ is monotone decreasing in $D$ when $A > 0$, we deduce that there is a threshold $D_c(A)$ such that the single spike pattern is stable for all $\tau \geq 0$ if $D \geq D_c(A)$. Substituting $y_0 = y_{0c}$ and using (2.21) and (3.7) yield the threshold parameter

$$q_{0c} = \frac{4 + 3\sqrt{3}}{11} \approx 0.83601, \quad (5.5)$$

with which $D_c(A)$ is found by solving the transcendental equation

$$\tanh D_c^{-1/2} = q_{0c}^{-1} A D_c^{-1/2}. \quad (5.6)$$

It is easy to see that if $A \geq q_{0c}$ then $D_c = \infty$ is the only positive solution. On the other hand, if $0 < A < q_{0c}$ then this equation has a unique positive solution that is monotone increasing in $A$ and satisfies $D_c \to 0^+$ as $A \to 0^+$ and $D_c \to \infty$ as $A \to q_{0c}$. In summary we deduce that the single spike pattern is stable for all $D > 0$ and $\tau \geq 0$ if $A \geq q_{0c}$, or for all $\tau \geq 0$ if $0 < D \leq D_c(A)$ and $0 < A < q_{0c}$. To determine the stability when $0 \leq A < q_{0c}$ and $D > D_c(A)$, we must consider the case $0 \leq y < y_{0c}$.

Next, we assume that $0 \leq y_0 < y_{0c}$. We begin by considering the shadow limit, defined by $D \to \infty$, for which $\mu(i\lambda_I) \sim 2(1 + i\tau\lambda_I)^{-1}$ and hence also

$$\text{Re}\mathcal{A}_{y_0}(i\lambda_I) \sim \frac{1}{2} \text{Re}\mathcal{F}_{y_0}(i\lambda_I), \quad \text{Im}\mathcal{A}_{y_0}(i\lambda_I) \sim \frac{\tau\lambda_I}{2} \text{Im}\mathcal{F}_{y_0}(i\lambda_I), \quad D \to \infty.$$
Since $\mathcal{F}_y(0) > 1/2$ and $\text{Re}\mathcal{F}_y(i\lambda I) \to 0$ as $\lambda I \to \infty$ (see “Appendix A” and accompanying Fig. 11), we deduce that there exists a solution to $\text{Re}\mathcal{A}_y(i\lambda I) = 0$. Moreover, in Fig. 11b we observe that when $\text{Re}\mathcal{F}_y(i\lambda I)$ is positive it is also monotone decreasing in $\lambda I$. Therefore, there exists a unique eigenvalue $\lambda^\infty$ and time constant $\tau^\infty = 2\text{Im}\mathcal{F}_y(i\lambda I)/\lambda^\infty$ such that $\mathcal{A}_y(i\lambda^\infty I) = 0$. Furthermore, since $\text{Im}\mathcal{A}_y(i\lambda^\infty I) \leq 0$ if $\tau \leq \tau^\infty$ we get

$$\Delta \arg \mathcal{A}_y(i\lambda I)^0 = \begin{cases} -5\pi/4, & \tau < \tau^\infty, \\ 3\pi/4, & \tau > \tau^\infty. \end{cases}$$

The single-boundary-spike solution therefore undergoes a Hopf bifurcation as $\tau$ exceeds the Hopf bifurcation threshold $\tau^\infty$. Using the shadow limit threshold as an initial guess, we numerically continue the Hopf bifurcation threshold for finite values of $D > 0$ to obtain the Hopf bifurcation threshold $\tau_h(D, A)$ and accompanying critical eigenvalue $\lambda = i\lambda_h(D, A)$ shown in Fig. 3b.

The above analysis, together with the plots of $\tau^\infty(A)$ and $\tau_h(D, A)$ in Fig. 3a, b, respectively, indicates that the single-boundary-spike solution is stabilized as $A > 0$ is increased. Additionally, if $A$ exceeds the threshold $q_{0c}$ given in (5.5), then the single boundary spike is stable independently of the parameters $\tau \geq 0$ and $D > 0$. We illustrate the onset of Hopf instabilities when $D = 5$ for $\tau = 1, 2, 7$ and $A = 0, 0.2, 0.4, 0.6$ by numerically computing the solution of (1.2) using FlexPDE 6 (PDE Solutions Inc.) and plotting $u(0, t)$ in Fig. 4. In particular, we observe that the single spike pattern is stabilized by increasing the boundary flux $A$. Additionally, our numerical simulations show good qualitative agreement with the Hopf bifurcation thresholds plotted in Fig. 3b.

### 5.2 Example 2: Two Boundary Spikes with $A = B \geq 0$

In this example, we investigate the role of equal boundary fluxes on the structure and stability of a two-boundary-spike pattern. Using the method of Sect. 2.1, a two-boundary-spike pattern is found by letting $l_L = l$ and $l_R = 1 - l$ and solving (2.22b), which is explicitly given by

$$\frac{\tanh \omega_0 l}{\eta(y_L) \cosh \omega_0 l} - \frac{\tanh \omega_0 (1 - l)}{\eta(y_R) \cosh \omega_0 (1 - l)} = 0, \quad (5.7)$$

for $0 < l < 1$ where $\eta$ is given by (2.6)) and $y_L$ and $y_R$ are given by (2.21). Note that by (2.19) the algebraic equation (5.7) is equivalent to

$$\frac{\xi_L}{\xi_R} = \frac{\cosh \omega_0 l}{\cosh \omega_0 (1 - l)}, \quad (5.8)$$

from which we deduce that $l \leq 1/2$ implies $\xi_L \leq \xi_R$. In particular, $l = 1/2$ solves (5.7) for all $A \geq 0$ and since in this case $\xi_L = \xi_R$ we refer to it as the symmetric solution. For the remainder of this example, we will construct asymmetric two-spike
Fig. 3 Hopf bifurcation threshold and accompanying eigenvalue for a single-boundary-spike solution with one-sided boundary flux \( A \geq 0 \) in (a) the shadow limit, \( D \to \infty \), and (b and c) for finite \( D > 0 \) at select values of \( 0 \leq A < q_0 \). In (a) the dashed vertical line corresponds to the threshold \( A = q_0 \) beyond which no Hopf instabilities occur.

patterns for which \( 0 < l < 1/2 \) (by symmetry the case \( l > 1/2 \) is identical) and then study the linear stability of both the symmetric and asymmetric patterns.

Before constructing asymmetric two-boundary-spike patterns for \( A \geq 0 \), we first recall the following existence result from Ward and Wei (2002) in the case \( A = 0 \).

Specifically, we let \( z = \omega_0l_L \) and \( \tilde{z} = \omega_0l_R \) so that when \( A = 0 \) the system (2.22) (and hence also (5.7)) is equivalent to

\[
    z + \tilde{z} = \omega_0, \quad b(z) = b(\tilde{z}), \quad b(z) = \frac{\tanh z}{\cosh z}.
\]

(5.9)

It follows from Result 2.3 (with \( k_1 = k_2 = 1, \mu = 1 \), and \( r = 1 \)) of Ward and Wei (2002) that (5.7) has a unique solution \( 0 < l < 1/2 \) if and only if

\[
    0 < D < D_{c1} \equiv [2 \log(1 + \sqrt{2})]^{-2} \approx 0.322.
\]

(5.10)

When \( A > 0 \) we solve (5.7) numerically and find that for given values of \( D \) and \( A > 0 \) it accepts zero, one, or two solutions in the range \( 0 < l < 1/2 \). Rather than solving (5.7) numerically for \( l \) as a function of \( A \) and \( D \), we found it more convenient to solve for \( A = A(D, l) \). The results of our numerical calculations are shown in Fig. 5a where we plot \( A = A(D, l) \) as well as the curve \( l = l_{\max}(D) \) along which \( A(D, l) \) is maximized for a fixed value of \( D \), and the curve \( l = l_{c1}(D) \) along which \( A(D, l_{c1}(D)) = A(D, 1/2) \) for \( D_{c1} < D < D_{c2} \approx 0.660 \) and \( l_{c1}(D) = 0 \) for \( 0 < D < D_{c1} \). Consequently, (5.7) has zero solutions in \( 0 < l < 1/2 \) if \( A > A_{\max}(D) \equiv A(D, l_{\max}(D)) \), whereas it has two solutions, one with \( l < l_{c1}(D) \) and the other with \( l > l_{c1}(D) \), if \( A_{\max}(D) > A > A_{c1}(D) \equiv A(D, l_{c1}(D)) \) for \( 0 < D < D_{c2} \). For all other values of \( D > 0 \) and \( A > 0 \), Eq. (5.7) has exactly one solution in \( 0 < l < 1/2 \). We summarize these existence thresholds in Fig. 5b where we note in particular that \( A > 0 \) greatly extends the range of \( D \) values over which asymmetric two-boundary-spike patterns exist.
Fig. 4 Plots of $u(0, t)$ for a one-boundary-spike solution with one-sided boundary flux $x = 0$ (i.e. $A \geq 0$ and $B = 0$) with $\varepsilon = 0.005$. Note that increasing the boundary flux $A$ stabilizes the single-boundary-spike solution for fixed values of $D$ and $\tau$.

Fig. 5 a Plots of $A = A(D, l)$ for the construction of asymmetric two boundary spikes in Example 2. The curve $l = l_{\text{max}}(D)$ indicates the values of $l$ at which $A(D, l)$ is maximized, while $l_{c1}(D) < 1/2$ indicates the values of $l$ at which $A(D, l)$ has the same value as $A(D, 1/2)$. The curve $l = l_{\text{max}}(D)$ also corresponds to the competition instability threshold for asymmetric two-boundary-spike patterns. If $l_{\text{max}}(D) < l < 1/2$ then the corresponding asymmetric pattern is unstable, whereas it is stable if $l < l_{\text{max}}(D)$. b Thresholds for the existence of zero, one, or two asymmetric two-boundary-spike solutions in the presence of equal boundary fluxes. The values of $A = A_{c1}(D)$ for $D_{c1} < D < D_{c2}$ and $A = A_{\text{max}}(D)$ for $D > D_{c2}$ correspond to the competition instability threshold for the symmetric two-boundary-spike pattern. It is linearly unstable for values of $A$ below this threshold, and stable otherwise. Note that no asymmetric solutions exist for $A = 0$ and $D > D_{c1}$.

We now consider the linear stability of both the symmetric and asymmetric two-boundary-spike patterns constructed above. Note that since $x_L = 0$ and $x_R = 1$ are fixed there are no slow drift dynamics and the linear stability of the two-spike patterns is completely determined by the $O(1)$ eigenvalues calculated from the NLEP (3.6a). Moreover, we assume that $\tau = 0$ so that no Hopf instabilities arise (see Example 1) and for which we can exclusively focus on zero eigenvalue crossing, or competition, instabilities. We proceed by first using the rigorous results of Sect. 4 to determine the linear stability of the symmetric two-spike patterns constructed above, and we will
then use the algebraic reduction outlined in Sect. 3.1 to determine the stability of the remaining asymmetric two-spike patterns.

Using (2.13b) and (2.19), the NLEP (3.6a) for the symmetric two-spike pattern constructed above is explicitly given by

\[
L \phi - 2 \omega_0 \tanh(\frac{\omega_0}{2}) \int_0^\infty w_c(y + y_0) G_{00} \phi \, dy w_c(y + y_0)^2 = \lambda \phi, \quad 0 < y < \infty; \quad \phi'(0) = 0,
\]

where

\[
\phi = \begin{pmatrix} \phi_1 \\ \phi_2 \end{pmatrix}, \quad G_{00} = \frac{1}{\omega_0 \sinh \omega_0} \begin{pmatrix} \cosh \omega_0 & 1 \\ 1 & \cosh \omega_0 \end{pmatrix}.
\]

The Green’s matrix is symmetric and of constant row sum and therefore has eigenvectors \((1, \pm 1)^T\). Substituting \(\phi = (\phi, \pm \phi)^T\) into the NLEP therefore yields two uncoupled scalar NLEPs of the form (4.1) with \(\mu = \mu_\pm\) where

\[
\mu_+ \equiv 2, \quad \mu_- \equiv 2 \tanh^2 \left(\frac{\omega_0}{2}\right).
\]

From Theorem 4.3 and accompanying Fig. 2b, we immediately deduce that the \(\phi_+\) mode is linearly stable. On the other hand, by Theorem 4.2 the \(\phi_-\) mode is unstable if \(\mu_- < \mu_c\), where \(\mu_c\) is defined by (4.14). We therefore calculate the competition instability threshold by numerically solving

\[
2 \tanh^2 \frac{\omega_0}{2} = \mu_c(y_0) \quad \text{where} \quad y_0 = y_L = y_R \quad \text{is the shift parameter given by (2.21) with} \quad l = 1/2.
\]

Our numerical calculations indicate that the resulting instability threshold coincides with the values

\[
A(D, 1/2) = \begin{cases} A_{c1}(D), & D_{c1} < D < D_{c2}, \\ A_{\max}(D), & D > D_{c2}, \end{cases}
\]

calculated above. In particular, the symmetric two-spike pattern is linearly unstable for all \(A < A(D, 1/2)\) when \(D > D_{c1}\). Furthermore, since \(\mu_c(y_0) < 0\) for \(y_0 > y_{0c}\) we determine from (2.22b) that there are no competition instabilities if

\[
A > \omega_0^{-1} q_{0c} \tanh(\omega_0/2),
\]

where \(q_{0c}\) is the threshold identified in Example 1 and is explicitly given by (5.5). Note that, analogous to the results in Example 1, in the shadow limit \((D \to \infty)\) there are no competition instabilities for the symmetric pattern if \(A > q_{0c}/2\) (see Fig. 5b). As in Sect. 4 we conjecture and have numerically supported that the symmetric two-spike pattern is linearly stable for \(\mu > \mu_c\) and hence for all \(A > A(D, 1/2)\). Finally, as is clear from Fig. 5b, increasing \(A > 0\) expands the range of \(D\) values over which the symmetric two-boundary-spike pattern is linearly stable.

For the asymmetric two-boundary-spike solutions constructed above, the NLEP (3.6a) is not diagonalizable since \(w_c(y + y_L) \neq w_c(y + y_R)\). We therefore can’t directly apply the rigorous results of Sect. 4. To determine the competition instability,
we instead use the algebraic reduction outlined in Sect. 3.1 and seek parameter values such that
\[ \det(\mathbb{I}_2 - 2\omega_0^2 G_{\omega_0} D_0) = 0 \]  
(5.15)
where \( \mathbb{I}_2 \) is the 2 × 2 identity matrix, \( G_{\omega_0} \) is the 2 × 2 Green’s matrix given in (5.11), and
\[ D_0 = \frac{1}{\omega_0} \begin{pmatrix} \tanh \omega_0 l \mathcal{F}_{yL}(0) & 0 \\ 0 & \tanh \omega_0 (1-l) \mathcal{F}_{yR}(0) \end{pmatrix}. \]  
(5.16)
Substituting the function \( A = A(D, l) \) calculated above into (5.15), we can solve for \( l \) as a function of \( D \) using standard numerical methods (specifically we used a combination of Scipy’s brentq and fsolve function in Python 3.6.8). Our computations indicate that the resulting competition instability threshold coincides with the curves \( l_{\text{max}}(D) \) for \( D > 0 \) and \( l = 1/2 \) for \( D_{c1} < D < D_{c2} \). In fact, we can show that this is the case explicitly by first differentiating the quasi-equilibrium equation \( B = 0 \) with respect to \( l \) to get
\[ \nabla_\xi B \left( \frac{\partial \xi}{\partial l} + \frac{\partial \xi}{\partial A} \frac{\partial A}{\partial l} \right) + \frac{\partial B}{\partial A} \frac{\partial A}{\partial l} = 0. \]  
(5.17)
Along the curve \( l_{\text{max}}(D) \) for \( D > 0 \) the function \( A(D, l) \) is maximized whereas, by symmetry, it is minimized along \( l = 1/2 \) for \( D_{c1} < D < D_{c2} \). In both cases \( \partial A/\partial l = 0 \) along these curves so that (5.17) becomes \( \nabla_\xi B \partial \xi / \partial l = 0 \). Differentiating (5.8) with respect to \( l \) implies that \( \partial \xi / \partial l \neq 0 \) and therefore we deduce that \( \nabla_\xi B \) is singular along \( l = l_{\text{max}}(D) \) and \( l = 1/2 \). By the discussion of Sect. 3.1, it follows that along these curves the algebraic Eq. (5.15) is satisfied and they therefore correspond to competition instability thresholds. Note in particular that the competition instability threshold along \( l = 1/2 \) corresponds to the competition instability threshold for the symmetric two-spike pattern. As an immediate consequence, it follows that \( A_{\text{max}} \to q_{oc}/2 \) as \( D \to \infty \).

To determine in which of the regions demarcated by the competition instability thresholds the asymmetric two-boundary-spike patterns are linearly stable and unstable, we calculate the stability of the asymmetric patterns along the \( A = 0 \) curve. As outlined in “Appendix C”, the asymmetric two-boundary-spike patterns when \( A = 0 \) are always linearly unstable, and therefore, we deduce that the asymmetric two-boundary-spike patterns in the region bounded by \( l = 1/2 \) and \( l = l_{\text{max}}(D) \) for \( 0 < D < D_{c2} \) are linearly unstable. On the other hand, numerically calculating the dominant eigenvalue of the NLEP (3.6a) (see “Appendix B” for description of numerical method) for select parameter values with \( l < l_{\text{max}}(D) \) we find that such asymmetric two-boundary-spike patterns are linearly stable. In particular, we note that in the region where there are two asymmetric patterns (i.e. for \( A_{c1}(D) < A < A_{\text{max}}(D) \)), the pattern with \( l > l_{\text{max}}(D) \) is linearly unstable while that with \( l < l_{\text{max}}(D) \) is linearly stable. Moreover, the single asymmetric two-boundary-spike pattern that exists for \( A < A_{\text{max}}(D) \) and \( D > D_{c1} \) is linearly stable.

Finally, we support our asymptotic predictions by numerically solving (1.2) using FlexPDE 6 (PDE Solutions Inc.) with parameters \( \varepsilon = 0.005 \) and \( \tau = 0.1 \) for select values of \( D \) and \( A \). Letting \( u_e \) and \( v_e \) be the any of the symmetric or asymmetric
two-boundary-spike patterns constructed above, we use

\[ u(x, 0) = (1 + 0.025 \cos(20x))u_e(x), \quad v(x, 0) = (1 + 0.025 \cos 20x)v_e(x), \]

as initial conditions and simulate (1.2) sufficiently long that the solution settles. The results of our numerical simulations indicate good agreement with the asymptotically calculated linear stability thresholds for both symmetric and asymmetric two-boundary-spike patterns. We include in Fig. 6 the results of our numerical calculations for select values of \( D \) and \( A \) indicated by black markers in Fig. 5a. In particular, in Fig. 6a we plot the spike heights at \( x_L = 0 \) (solid) and \( x_R = 1 \) (dashed) for \( D = 0.30 \) and \( A = 0.02 \) with initial conditions given by the two-boundary-spike pattern constructed with \( l = 0.5 \) which is symmetric and predicted to be stable, as well as \( l = 0.22 \) and \( l = 0.05 \) which are both asymmetric but predicted to be linearly unstable and stable, respectively. It is clear from the resulting plots that our asymptotic predictions hold in this numerical simulations. Additionally, we observe that the unstable asymmetric two-spike pattern tends toward the linearly stable pattern. We observed this trend for all our numerical simulations in which \( l_{\text{max}} < l < 1/2 \) though predicting this long-time behaviour analytically is beyond the scope of this paper. Similarly, we numerically simulate the dynamics of a symmetric and asymmetric two-boundary-spike pattern when \( D = 0.60 \) and \( A = 0.08 \) (Fig. 6b) and when \( D = 0.90 \) and \( A = 0.18 \) (Fig. 6c). In both cases the symmetric and asymmetric patterns are predicted to be linearly unstable and stable, respectively, which agrees with the outcomes observed in our numerical simulations.

5.3 Example 3: Two Boundary Spikes with a One-Sided Flux (A ≥ 0 and B = 0)

In this example we investigate the effect of a one-sided boundary flux (\( A \geq 0 \) and \( B = 0 \)) on the structure and linear stability of a two-boundary-spike pattern. Letting
The corresponding existence thresholds of the same results from Ward and Wei (2002) summarized in Example 2.

In the regions $1 < l < 2$, respectively. Note that since the horizontal asymptote is indicated in Fig. 7c.

Proceeding as in Example 2, we first numerically calculate $A_{\text{max}}$ and $A_{\text{bot}}$ for all $D > 0$ provided that $A < A_{\text{max}}$. Furthermore, by letting $D \to \infty$ in (5.19) we numerically calculate $A_{\text{max}} \to 0.13772$ and $A_{\text{bot}} \to 0.16148$ as $D \to \infty$ and this horizontal asymptote is indicated in Fig. 7c.

Next, we consider the linear stability of the two-boundary-spike patterns constructed above when $\tau = 0$. In particular, we restrict our attention to competition instabilities which arise through a zero eigenvalue crossing. Proceeding as in Example 2, we first deduce that both $l = l_{\text{max}}$ and $l = l_{\text{bot}}$ yield a competition instability threshold. Furthermore, we verify that these are the only competition instability thresholds
Fig. 8 Numerical simulations for Example 2 when $\xi_L > \xi_R$. (a) Outcome of numerical simulation of (1.2) starting from the asymmetric two-boundary-spike pattern constructed using the indicated values of $D$, $l$, and $A$. Blue and orange markers indicate the two-boundary-spike pattern settled to the stable two-spike pattern (i.e. with $l < l_{\text{top}}^\text{max}(D)$) or collapsed to a single spike pattern, respectively. Black dots indicate values of $D$, $A$, and $l$ for which the spike heights are plotted over time in Figures (b) and (c). The left and right dashed vertical lines indicate $D = 0.054$ and $D = 0.204$, respectively. In b and c we plot spike heights at $x = 0$ (solid) and $x = 1$ (dashed) at given values of $D$ and $A$ and with initial condition specified by indicated value of $l$.

by numerically computing the algebraic Eq. (3.14) where $\Theta_0$ and $D_0$ are given by (5.11) and (5.16), respectively. Since all asymmetric two-boundary-spike patterns when $A = 0$ are unstable with respect to competition instabilities (see Example 2 and “Appendix C”), we immediately deduce that all asymmetric two-boundary-spike patterns with $\xi_L > \xi_R$ and $\xi_L < \xi_R$ are linearly unstable when $l > l_{\text{top}}^\text{max}(D)$ and $l > l_{\text{bot}}^\text{max}(D)$, respectively, and are linearly stable otherwise. In particular, the nonzero boundary flux $A > 0$ both extends the range of parameter values for which asymmetric patterns exists and are linearly stable.

To support our asymptotic predictions, we numerically calculate solutions to (1.2) when $\epsilon = 0.005$ and $\tau = 0.1$ for select values of $D$ and $A < \max\{A_{\text{top}}^\text{max}(D), A_{\text{bot}}^\text{max}(D)\}$. For each pair $(D, A)$ we let $0 < l < 1$ be any of the values for which $A(D, l) = A$ and then let $(u_e(x), v_e(x))$ be the corresponding equilibrium pattern constructed above. Using (5.18) as an initial condition, we then solve (1.2) numerically using FlexPDE 6 (PDE Solutions Inc.). The results of our numerical simulations are illustrated in Figs. 8 and 9 when $l$ is chosen to be in $1/2 < l < 1$ and $0 < l < 1/2$, respectively. Specifically, in Fig. 8a (resp. 9a) we indicate with a blue or orange marker, respectively, whether the solution settles (after simulating for $0 < t < 200$) to the asymptotically predicted stable equilibrium with $l < l_{\text{top}}^\text{max}(D)$ (resp. $l < l_{\text{bot}}^\text{max}(D)$) or to a one-boundary-spike solution in which the spike at $x = 1$ collapses, respectively. In Figs. 8b, c (resp. 9b, c) we show the spike heights as functions of time at select values of $A$ and $D$ using an unstable and stable value of $l$ in $1/2 < l < 1$ (resp. $0 < l < 1/2$) to construct the initial condition (see captions for more details). The results of these numerical simulations are in good agreement with our asymptotic predictions. However, we comment that in the numerical outcomes shown in Fig. 8a some of the asymmetric patterns which are predicted to be stable collapse. We expect that this error is due to a combination of small errors from the
Fig. 9 Numerical simulations for Example 2 when $\xi_L < \xi_R$. a Outcome of numerical simulation of (1.2) starting from the asymmetric two-boundary-spike pattern constructed using the indicated values of $D$, $l$, and $A$. Blue and orange markers indicate the two-boundary-spike pattern settled to the stable two-spike pattern (i.e. with $l < l_{\text{bot max}}(D)$) or collapsed to a single spike pattern, respectively. Black dots indicate values of $D$, $A$, and $l$ for which the spike heights are plotted over time in (b) and (c). The left and right dashed vertical lines indicate $D = 0.592$ and $D = 1.508$, respectively. In b and c we plot spike heights at $x = 0$ (solid) and $x = 1$ (dashed) at given values of $D$ and $A$ and with initial condition specified by indicated value of $l$.

5.4 Example 4: One Boundary and Interior Spike with One-Sided Feed ($A \geq 0$, $B = 0$)

In this final example, we extend the results of Example 3 to the case where there is one boundary spike at $x_L = 0$ and one interior spike at $0 < x_1 < 1$. The asymptotic construction of the resulting two spike patterns, as well as the analysis of their linear stability on an $O(1)$ timescale, proceeds as in the previous example. However, since $x_1$ is an equilibrium of the slow dynamics Eq. (2.16), we must now also determine the stability of the two-spike pattern on an $O(\epsilon^{-2})$ timescale by analysing the linearization of (2.16). We remark that an alternative approach to determine the stability of multi-spike patterns on an $O(\epsilon^{-2})$ timescale is to calculate the $O(\epsilon^2)$ eigenvalues of the linearization (3.1) though we do not pursue this approach further (see for example (Iron et al. 2001) for the analysis of $O(\epsilon^2)$ eigenvalues).

Using the method of Sect. 2.1, with $l_L = l$ and $l_1 = (1 - l)/2$ Eq. (2.22b) becomes

$$\frac{\tanh \omega_0 l}{\eta(y_L) \cosh \omega_0 l} - \frac{\tanh \omega_0 \frac{1-l}{2}}{3 \cosh \omega_0 \frac{1-l}{2}} = 0,$$

(5.20)

which is to be solved for $0 < l < 1$ where $\eta(y_L)$ and $y_L = y_0(\omega_0 A / \tanh \omega_0 l)$ are given by (2.6) and (2.21), respectively. As in the previous examples, we observe that $\xi_L = \xi_1$ if and only if $l = 1/3$ which is a solution to (5.20) if and only if $A = 0$. In particular, together with the discussion in Example 3 we deduce that there are no symmetric two-spike patterns when there is a one-sided positive boundary flux $A > 0$. 

As in the previous examples, we also note that $\xi_L \leq \xi_1$ if $l \leq 1/3$. Next, we note that since $l_1 = (1-l)/2$ the relevant asymmetric equilibrium results for $A = 0$ from Ward and Wei (2002) summarized in Example 2 must be modified. In particular, letting $z = \omega_0 l_L$ and $\tilde{z} = \omega_0 l_1$, Eqs. (2.22a) and (2.22b) when $A = 0$ become

$$z + 2\tilde{z} = \omega_0, \quad b(z) = b(\tilde{z}),$$

(5.21)

where $b(z)$ is given in (5.9). Then, Result 2.3 of Ward and Wei (2002) (with $k_1 = 1$ and $k_2 = 2$) implies that a unique asymmetric two-spike solution with $z \leq \tilde{z}$ exists if and only if

$$D < D_m \equiv [3 \log(1 + \sqrt{2})]^{-2} \approx 0.143,$$

(5.22)

whereas Result 2.4 of Ward and Wei (2002) (with $k_1 = 2$ and $k_2 = 1$) implies that there are either exactly one or two asymmetric two-spike solutions with $z > \tilde{z}$ if and only if

$$D < D_m \quad \text{or} \quad D_m < D < D_{m1} \equiv [2 \sinh^{-1}(1/2) + \sinh^{-1}(2)]^{-2} \approx 0.17274,$$

(5.23)

respectively. Proceeding as in Examples 2 and 3, we can then numerically calculate $A = A(D, l)$ from (5.20) in the appropriate regions with $0 < l < 1/3$ and $1/3 < l < 1$. In Figs. 10a and 10b we plot $A = A(D, l)$ together with the curves $l = l_{\text{max}}^{\text{top}}(D)$ and $l = l_{\text{max}}^{\text{bot}}(D)$ along which $A(D, l)$ is maximized. The resulting existence thresholds $A_{\text{max}}^{\text{top}}(D) \equiv A(D, l_{\text{max}}^{\text{top}}(D))$ and $A_{\text{max}}^{\text{bot}}(D) \equiv A(D, l_{\text{max}}^{\text{bot}}(D))$ are plotted in Fig. 10c. In particular, a two-spike pattern with a two-spike pattern consisting of one boundary and one interior spike with $\xi_L > \xi_1$ only exists for $D < D_{m1}$ when $A < A_{\text{max}}^{\text{top}}(D)$, whereas such a two-spike pattern with $\xi_L < \xi_1$ exists for all $D > 0$ provided that $A < A_{\text{max}}^{\text{bot}}(D)$. Finally, by taking the limit $D \to \infty$ in (5.20) we numerically obtain the limiting values $l_{\text{max}}^{\text{top}}(D) \to 0.0857$ and $A_{\text{max}}^{\text{bot}}(D) \to 0.087174$ as $D \to \infty$.

Next, we consider the linear stability of the two-spike patterns constructed above on an $O(1)$ timescale. As in Examples 2 and 3 we focus exclusively on competition insta-
bilities by assuming that $\tau = 0$ and seeking a zero eigenvalue crossing of the NLEP (3.6a). In contrast to Examples 2 and 3, above the relevant competition instability threshold does not necessarily coincide with the curves $l = l_{\text{top}}^{\text{max}}(D)$ and $l = l_{\text{bot}}^{\text{max}}$. Indeed, fixing $D > 0$ and differentiating the quasi-equilibrium equation $B = 0$ with respect to $l$ gives

$$\nabla_{\xi} B \left( \frac{\partial \xi}{\partial l} + \frac{\partial \xi}{\partial A} \frac{\partial A}{\partial l} \right) + \frac{\partial B}{\partial A} \frac{\partial A}{\partial l} + \frac{\partial B}{\partial x_1} \frac{dx_1}{dl} = 0, \quad (5.24)$$

which along either $l = l_{\text{top}}^{\text{max}}(D)$ or $l = l_{\text{bot}}^{\text{max}}(D)$ reduces to

$$\nabla_{\xi} B \frac{\partial \xi}{\partial l} = -\frac{1}{2} \frac{\partial B}{\partial x_1}.$$

Since $\partial B / \partial x_1 \neq 0$ it follows that $\nabla_{\xi} B$ is not necessarily singular along $l_{\text{top}}^{\text{max}}(D)$ or $l_{\text{bot}}^{\text{max}}(D)$ and in particular these curves need not coincide with the competition instability thresholds. Note, however, that $\partial B / \partial x_1 \to 0$ as $D \to \infty$ and therefore the competition instability threshold will coincide with $l_{\text{bot}}^{\text{max}}(D)$ but only in the limit $D \to \infty$. Thus, to calculate the appropriate competition instability thresholds we use the algebraic reduction of Sect. 3.1 and numerically solve (3.14) when $\lambda = 0$ and where the matrices $G_{\omega_0}$ and $D_{\omega_0}$ are, respectively, given by

$$G_{\omega_0} = \frac{1}{\omega_0 \sinh \omega_0} \left( \begin{array}{cc} \cosh \omega_0 & \cosh \omega_0 (1 - x_1) \\
\cosh \omega_0 (1 - x_1) & \cosh \omega_0 x_1 \cosh \omega_0 (1 - x_1) \end{array} \right), \quad (5.25a)$$

and

$$D_0 = \frac{1}{\omega_0} \left( \begin{array}{cc} \tanh (\omega_0 l) F_yL(0) & 0 \\
0 & 2 \tanh (\omega_0 \frac{1 - l}{2}) \varphi_y(0) \end{array} \right). \quad (5.25b)$$

The resulting competition instability threshold $l_{\text{comp}}^{\text{top}}(D)$ when $\xi_L > \xi_1$ as well as $l_{\text{comp}}^{\text{bot}}(D) (i = 1, 2)$ when $\xi_L < \xi_1$ is indicated in Fig. 10a, b, respectively. Additionally, in Fig. 10c we have plotted $A_{\text{comp}}^{\text{top}}(D) \equiv A(D, l_{\text{comp}}^{\text{top}}(D))$ and $A_{\text{comp}}^{\text{bot}}(D) \equiv A(D, l_{\text{comp}}^{\text{bot}}(D)) (i = 1, 2)$. Finally, the stability result along the $A = 0$ curve calculated in “Appendix C” implies that the two-spike pattern with $\xi_L > \xi_1$ is linearly unstable on an $O(1)$ timescale when $l > l_{\text{comp}}^{\text{top}}(D)$, and similarly when $\xi_L < \xi_1$ the two-spike pattern is linearly unstable in the region bounded by the curves $l = l_{\text{comp},1}^{\text{bot}}(D)$ and $l = l_{\text{comp},2}^{\text{bot}}(D)$.

Next, we consider the linear stability of the two-spike patterns on an $O(\epsilon^{-2})$ timescale. We explicitly calculate the right-hand side of (2.16) by first calculating
\[
\left\langle \partial_x G_{\omega_0} (x, x_1) \right\rangle_{x_1} = \frac{\sinh \omega_0 (2x_1 - 1)}{\sinh \omega_0}, \quad \partial_x G_{\omega_0} (x, 0) \Big|_{x_1} = -\frac{\sinh \omega_0 (1 - x_1)}{\sinh \omega_0},
\]

and rearranging the quasi-equilibrium Eq. (2.15a) as

\[
\frac{\omega_0^2 \xi^2 (yL)}{\xi_1} = \frac{1 - 6 \omega_0^2 \xi_1 G_{\omega_0} (x_1, x_1)}{G_{\omega_0} (x_1, 0)}.
\]

so that (2.16) becomes

\[
\frac{1}{\varepsilon^2} \frac{dx_1}{dt} = -6 \omega_0^2 f (x_1), \quad f (x_1, \xi_1) = \xi_1 - \frac{\tanh \omega_0 (1 - x_1)}{3 \omega_0}, \quad (5.26)
\]

where \(\xi_1\) together with \(\xi_L\) and \(y_L\) are functions of \(x_1\) found by solving (2.15a) and (2.3). Note that the asymmetric two-spike equilibrium solutions constructed above using the method of Sect. 2.1 immediately satisfy (2.3). Numerically evaluating \(f (x_1)\), we find that the drift instability thresholds for which \(f' (x_1) = 0\) coincide with the curves \(l_{\text{max}}^{\text{top}} (D)\) and \(l_{\text{max}}^{\text{bot}} (D)\). In fact, we can show that this is the case analytically by first evaluating (5.24) along either \(l_{\text{max}}^{\text{top}} (D)\) or \(l_{\text{max}}^{\text{bot}} (D)\) to get

\[
\nabla \xi B \frac{\partial \xi}{\partial x_1} = -\frac{\partial B}{\partial x_1}, \quad (5.28)
\]

where \(\partial \xi_1 / \partial x_1\) is calculated by first differentiating the quasi-equilibrium equation \(B = 0\) with respect to \(x_1\)

\[
\nabla \xi B \frac{\partial \xi}{\partial x_1} = -\frac{\partial B}{\partial x_1}, \quad (5.28)
\]

and then solving for \(\partial \xi / \partial x_1\) which we can do since we are assuming the two-spike pattern is stable on an \(O(1)\) timescale and the matrix \(\nabla \xi B\) is therefore invertible.

Numerically evaluating \(f' (x_1)\), we find that the drift instability thresholds for which \(f' (x_1) = 0\) coincide with the curves \(l_{\text{max}}^{\text{top}} (D)\) and \(l_{\text{max}}^{\text{bot}} (D)\). In fact, we can show that this is the case analytically by first evaluating (5.24) along either \(l_{\text{max}}^{\text{top}} (D)\) or \(l_{\text{max}}^{\text{bot}} (D)\) to get

\[
\nabla \xi B \frac{\partial \xi}{\partial l} = -\frac{1}{2} \frac{\partial B}{\partial x_1}. \quad (5.29)
\]

Since the competition instability thresholds do not coincide with the curves \(l_{\text{max}}^{\text{top}} (D)\) and \(l_{\text{max}}^{\text{bot}} (D)\), the matrix \(\nabla \xi B\) is invertible along these curves and comparing (5.28) with (5.29) we obtain

\[
\frac{\partial \xi_1}{\partial x_1} = 2 \frac{\partial \xi}{\partial l} = -\frac{l}{3} \text{sech}^2 \omega_0 \frac{1 - l}{2} = -\frac{1}{3} \text{sech}^2 \omega_0 (1 - x_1). \quad (5.30)
\]

In particular, \(f' (x_1) = 0\) along the curves \(l = l_{\text{max}}^{\text{top}} (D)\) and \(l_{\text{max}}^{\text{bot}} (D)\). Numerically evaluating \(f' (x_1)\) at select values of \(l\) above and below these thresholds, we determine that the two-spike patterns constructed above with \(\xi_L > \xi_1\) or \(\xi_L < \xi_1\) are linearly stable on an \(O(\varepsilon^{-2})\) timescale if and only if \(l < l_{\text{max}}^{\text{top}} (D)\) or \(l > l_{\text{max}}^{\text{bot}} (D)\), respectively.
As in the previous examples, we performed full numerical simulations of (1.2) with FlexPDE 6 (PDE Solutions Inc.) to support our asymptotic predictions. Our numerical simulations were found to strongly agree with the predicted stability thresholds. In particular, we observed the following dynamics. For values of \( l \) that are stable with respect to both competition and drift instabilities, that is when \( l < l_{\text{top max}} \) (resp. \( l < l_{\text{bot max}} \)) for \( l > 1/3 \) (resp. \( l < 1/2 \)) the two-spike pattern was observed to be stable. In the remaining regions (both stable and unstable with respect to competition instabilities), we observed that the interior spike either collapses and the boundary spike collapses to the one-boundary-spike solution, or else the interior spike changes height to the height of the stable pattern and then slowly drifts toward the location of the interior spike in the stable two-spike solution. As in Example 3, we noticed sensitivity to the competition instability threshold which we believe to be primarily due to the flatness of \( A \) in this region.

6 Discussion

We have extended the asymptotic theory developed for the singularly perturbed one-dimensional GM model to include the possibility of inhomogeneous Neumann boundary conditions for the activator. Additionally, we have rigorously established partial stability and instability results for a class of shifted NLEPs. While the shifted NLEPs we considered are closely related to those in Maini et al. (2007), we highlight that the difference in sign of the shift parameter leads substantial differences in the stability properties of the NLEP. Finally, we considered four examples to illustrate the asymptotic and rigorous theory as well as to explore the behaviour of the GM system with nonzero flux boundary conditions. For a one-boundary-spike solution, we found that the nonzero Neumann boundary condition improves the stability with respect to Hopf instabilities. Moreover, by considering a two-boundary-spike pattern with equal inhomogeneous boundary fluxes we illustrated that the nonzero boundary flux improves the stability of symmetric two-spike patterns and also extends the region of \( D > 0 \) values for which asymmetric patterns exist provided that \( A = B > 0 \) is not larger than a computed threshold. Similar results were obtained when considering a one-sided boundary flux for which we considered patterns where both spikes concentrate on the boundary and where one concentrates on the boundary and the other in the interior. In each of our two-spike pattern examples, we observed that there are two asymmetric patterns, where one is always linearly unstable and the other is always linearly stable. In a sense, the stable asymmetric pattern can be considered a boundary layer solution that is a direct consequence of the inhomogeneous Neumann boundary condition. In particular, its existence is mandated by the inhomogeneous boundary condition which makes a direct comparison with asymmetric spike patterns in the absence of boundary flux conditions difficult. However, our results illustrate that inhomogeneities at the boundaries predispose the GM to forming patterns concentrating at the boundaries in both symmetric and asymmetric configurations. We believe the distinction between interior and boundary-layer-like localized pattern will play a key role in understanding more complicated mathematical models such as those.
incorporating bulk-surface coupling (see Figure 3 in Madzvamuse et al. (2015) for an example of a boundary-layer-type pattern in a bulk-surface model).

There are several key open problems and directions for future research. First, our rigorous results for the shifted NLEP do not provide tight bounds for regions of stability and instability. Specifically, in the small shift case we have determined that the NLEP is unstable if \( \mu < \mu_c(y_0) \), and stable if \( \mu_1(y_0) < \mu < \mu_2(y_0) \) where we have highlighted that \( \mu_c(y_0) < \mu_1(y_0) \). As indicated in Sect. 4, we conjecture that in fact the shifted NLEP is stable for all \( \mu > \mu_c \) and in “Appendix B” we provide numerical support for this conjecture. Proving this conjecture is our first open problem. In addition, to calculate the stability of asymmetric patterns for which the shift parameters are different we could not directly use the rigorous results established in Sect. 4 since the NLEP (3.6a) could not be diagonalized. The development of a rigorous stability theory for NLEP systems of this form is an additional direction for future research.

One of the key insights from our investigation of a two-boundary-spike configuration is that the presence of equal or one-sided boundary fluxes for the activator greatly extends the range of diffusivity values for which asymmetric patterns exist and are linearly stable. This expanded region of existence and stability parallels that found when spatially inhomogeneous precursors are included in the GM model. However, it can be argued that introducing inhomogeneous flux conditions provides a simpler alternative for generating asymmetric patterns. This warrants further research into the role of inhomogeneous boundary conditions for the activator in both activator–inhibitor and activator–substrate models in one-, two-, and three-dimensional domains.

**Appendix A. Large \( \lambda \) Asymptotics of \( \mathcal{F}_{y_0}(i\lambda) \)**

In this appendix, we determine some key properties of \( \mathcal{F}_{y_0}(\lambda) \) defined in (3.12). Recalling (3.13), in Fig. 11a we plot \( \mathcal{F}_{y_0}(0) \) versus \( y_0 \geq 0 \). Next, we calculate the
limiting behaviour of \( \mathcal{F}_{y_0}(i \lambda I) \) as \( \lambda I \to \infty \). First, we let \( (\mathcal{L}_{y_0} - i \lambda I)^{-1} w_c(y + y_0)^2 = \Phi_R + i \Phi_I \) where \( \Phi_R \) and \( \Phi_I \) solve

\[
\mathcal{L}_{y_0} \Phi_R + \lambda I \Phi_I = w_c(y + y_0)^2, \quad \mathcal{L}_{y_0} \Phi_I - \lambda I \Phi_R = 0, \quad \text{(A.1)}
\]

with the boundary conditions \( \Phi'_R(0) = \Phi'_I(0) \) and \( \Phi_R, \Phi_L \to 0 \) as \( y \to \infty \). Taking \( \lambda I \gg 1 \) and assuming that \( y = \mathcal{O}(1) \), we obtain

\[
\Phi_I(y) \sim \frac{1}{\lambda I} w_c(y + y_0)^2, \quad \Phi_R(y) \sim \frac{1}{\lambda I} \mathcal{L}_{y_0} \Phi_I = \frac{1}{\lambda I^2} (2w'_c(y + y_0)^2 + w_c(y + y_0)^2).
\]

If \( y_0 > 0 \) then \( \Phi'_R(0) = 0 \) and \( \Phi'_I(0) = 0 \) are not satisfied and we must therefore consider the boundary layer at \( y = 0 \). Setting \( z = \lambda I^{1/2} y \), we consider the inner expansion \( \Phi_R \sim \widetilde{\Phi}_R(z) \) and \( \Phi_I \sim \widetilde{\Phi}_I(z) \) where \( \widetilde{\Phi}_I \) satisfies

\[
\frac{d^4 \widetilde{\Phi}_I}{dz^4} + \widetilde{\Phi}_I = \frac{1}{\lambda I} w_c(y_0)^2 \quad z > 0; \quad \frac{d^2 \widetilde{\Phi}_I}{dz^2} = \frac{d^3 \widetilde{\Phi}_I}{dz^3} = 0, \quad z = 0,
\]

and must be matched to the outer, \( y = \mathcal{O}(1) \), solution through the far-field behaviour

\[
\widetilde{\Phi}_I \sim \frac{1}{\lambda I} w_c(y_0)^2, \quad \frac{d^2 \widetilde{\Phi}_I}{dz^2} \sim \frac{1}{\lambda I^2} (2w'_c(y + y_0)^2 + w_c(y + y_0)^2), \quad z \to \infty.
\]

It is clear that the leading order solution is \( \widetilde{\Phi}_I(z) \sim \lambda I^{-1} w_c(y_0)^2 \). The constant behaviour of \( \Phi_I \) at the boundary layer therefore does not contribute to the leading order behaviour of the integral

\[
\int_0^\infty w_c(y + y_0) \Phi_I(y) dy \sim \lambda I^{-1} \int_0^\infty w_c(y + y_0)^3 dy, \quad \lambda I \gg 1.
\]

Moreover, multiplying the right equation in (A.1) by \( w_c(y + y_0) \) and integrating we calculate

\[
\int_0^\infty w_c(y + y_0) \Phi_R(y) dy = \frac{1}{\lambda I} \left( w'_c(y_0) \Phi_I(0) + \int_0^\infty \Phi_I \mathcal{L}_{y_0} w_c(y + y_0) dy \right)
\sim \frac{1}{\lambda I^2} \left( w'_c(y_0) w_c(y_0)^2 + \int_0^\infty w_c(y + y_0)^4 dy \right),
\]

for \( \lambda I \gg 1 \) where we have used \( \mathcal{L}_{y_0} w_c(y + y_0) = w_c(y + y_0)^2 \). In summary, we have the large \( \lambda I \) asymptotics.
\[
\mathcal{F}_{y_0}(i\lambda_I) \sim \frac{1}{\lambda_I^2} \frac{w_c'(y_0)w_c(y_0)^2 + \int_0^\infty w_c(y+y_0)^4dy}{\int_0^\infty w_c(y+y_0)^2dy} + \frac{i}{\lambda_I} \frac{\int_0^\infty w_c(y+y_0)^3dy}{\int_0^\infty w_c(y+y_0)^2dy}, \quad \lambda_I \gg 1.
\] (A.2)

Note that the real part changes from positive to negative as \( y_0 \) exceeds \( y_0 \approx 1.0487 \).

In Fig. 11b, c we plot the real and imaginary parts of \( \mathcal{F}_{y_0}(i\lambda_I) \), respectively, for select values of \( y_0 \). In addition, we have included the large \( \lambda_I \) asymptotics which indicate close agreement for moderately large values of \( \lambda_I \).

### Appendix B. Numerical Support for Stability Conjecture

In this appendix, we provide numerical support for the conjecture that the shifted NLEP (4.1) has a stable spectrum when \( \mu > \mu_c(y_0) \) by numerically calculating the dominant eigenvalue of the NLEP for \( 0 \leq y_0 \leq 1.5 \) and \( 0 \leq \mu \leq 10 \). The numerical calculation of the spectrum was performed by truncating the domain \( 0 < y < \infty \) to \( 0 < y < 20 \) and discretizing it with 600 uniformly distributed points. Then, we used a finite difference approximation for the second derivatives and a trapezoidal rule discretization for the integral term to approximate the NLEP (4.1) with a discrete matrix eigenvalue problem. We then numerically calculated the dominant eigenvalue of matrix by using the eigenfunction in the Python scipy.linalg library for our numerical computation of the dominant eigenvalue. In Fig. 12a we plot \( \text{Re}\lambda_0 \) versus \( y_0 \) and \( \mu \). We observe the real part of the dominant eigenvalue is negative when \( \mu \) exceeds the threshold \( \mu_c(y_0) \). Additionally, in Fig. 12b we plot \( \Lambda_0 - \text{Re}(\lambda_0) \) for the same range of \( y_0 \) and \( \mu \) values. We observe that this difference is non-negative which suggest that \( \text{Re}\lambda_0 \leq \Lambda_0 \).

![Fig. 12](image_url)

**Fig. 12** a Plot of the real part of the dominant eigenvalue of the shifted NLEP (4.1) versus shift parameter \( y_0 \) and multiplier \( \mu \). The dotted red line corresponds to the critical threshold \( \mu_c \) defined in (4.14) and the solid dark line is the zero contour of \( \text{Re}\lambda_0 \). b Plot of the difference between dominant eigenvalues of \( \mathcal{L}_{y_0} \) and the NLEP (4.1)
Appendix C. Stability of Asymmetric Two-Boundary-Spike Pattern when \( A = 0 \)

Previous results on the stability of asymmetric two spike equilibria of (1.2) when \( A = 0 \) have focused exclusively on interior multi-spike solutions (Ward and Wei 2002). To compare the \( A = B = 0 \) theory with our results obtained in Examples 2–4, we include here a summary of the stability of an asymmetric two-spike solution where one spike concentrates at \( x = 0 \) and the other concentrates at either \( x = 1 \) or in the interior \( 0 < x < 1 \). In both cases the NLEP (3.6a) with \( A = 0 \) can be written as

\[
\mathcal{L}_0 \phi - 2 w_c(y)^2 \int_{0}^{\infty} \frac{w_c(y)}{w_c(y)^2} dy \phi = \lambda \phi, \tag{C.1}
\]

where for two boundary spikes we let

\[
\mathcal{E} = \mathcal{E}_{bb} \equiv \begin{pmatrix} \coth \omega_0 \tanh \omega_0 l & \csch \omega_0 \coth \omega_0 (1 - l) \\ \csch \omega_0 \tanh \omega_0 l & \coth \omega_0 \tanh \omega_0 (1 - l) \end{pmatrix}, \tag{C.2}
\]

and in the case of one boundary and one interior spike we let

\[
\mathcal{E} = \mathcal{E}_{bi} \equiv \begin{pmatrix} \coth \omega_0 \tanh \omega_0 l & 2 \csch \omega_0 \sinh \omega_0 \frac{1 - l}{2} \\ \csch \omega_0 \tanh \omega_0 l \cosh \omega_0 \frac{1 - l}{2} & 2 \csch \omega_0 \cosh \omega_0 \frac{1 + l}{2} \sinh \omega_0 \frac{1 - l}{2} \end{pmatrix}. \tag{C.3}
\]

It is then straightforward to verify that \( \sigma = 1 \) is an eigenvalue of both matrices \( \mathcal{E}_{bb} \) and \( \mathcal{E}_{bi} \). The remaining eigenvalue in each case is then given by the determinant. By diagonalizing \( \mathcal{E} \) the NLEP (C.1) can therefore be written as (4.1) with \( \mu = 2 \) as well.

![NLEP Multiplier for Two-Spike Pattern](A)

![Asymmetric Two-Spike Patterns](B)

**Fig. 13**  a Multiplier \( \mu \) in the NLEP for a two-spike solution when \( A = B = 0 \) and where the two spikes concentrate either at the boundaries or else one spike concentrates at the boundary and the other in the interior. b Relationship between \( l \) and \( D \) in the gluing method used to construct a two-spike solution when \( A = B = 0 \) and where either both spikes concentrate at the boundaries, or one spike concentrates at the boundary and the other in the interior.
as with $\mu = 2 \det \mathcal{E}_{bb}$ and $\mu = 2 \det \mathcal{E}_{bi}$ for the boundary–boundary and boundary–interior cases, respectively. Since the $A = B = 0$ stability theory implies that the NLEP (4.1) is stable if and only if $\mu > 1$ (Wei 1999) we immediately deduce that the $\mu = 2$ modes are stable in both the boundary–boundary and boundary–interior cases.

To determine the stability of the remaining modes, we explicitly calculate

$$
\det \mathcal{E}_{bb} = \tanh \omega_0 \tanh \omega_0 (1 - l), \\
\det \mathcal{E}_{bi} = 2 \frac{\tanh \omega_0 \sinh \omega_0 \frac{1-l}{2} \sinh \omega_0 \frac{1+l}{2}}{\sinh \omega_0}.
$$

(C.4)

Finally, for the boundary–boundary and boundary–interior cases we solve (5.7) and (5.20) for $D = D(l)$, respectively, and the resulting values of $2 \det \mathcal{E}_{bb}$ and $2 \det \mathcal{E}_{bi}$ for $0 < l < 1$ are shown in Fig. 13a. In particular, the asymmetric pattern with two boundary spikes is always linearly unstable, while the pattern with one boundary and one interior spike has a region of stability (with respect to the $O(1)$ eigenvalues). In Fig. 13b we plot $l = l(D)$ (cf. Figs. 7 and 10) for both two-spike configurations, indicating where the pattern is stable (solid line) and unstable (dashed line).
