Evaluation of the Clinical Performance of a Novel Chemiluminescent Immunoassay for Detection of Anticardiolipin and Anti-Beta2-Glycoprotein 1 Antibodies in the Diagnosis of Antiphospholipid Syndrome

Shulan Zhang, MD, Ziyan Wu, MD, Ping Li, MD, Yina Bai, BS, Fengchun Zhang, MD, and Yongzhe Li, MD

Abstract: Detection of antiphospholipid antibodies represents the first-line approach for diagnosis of antiphospholipid syndrome (APS). In this study, we evaluated the clinical performance of a novel chemiluminescence assay (CIA) in detection of IgG/IgM/IgA anti-cardiolipin (aCL) and IgG/IgM/IgA anti-beta2 glycoprotein 1 (aβ2GP1) antibodies and to compare it with commercial enzyme-linked immunosorbent assay (ELISA) kits from the same manufacturer.

A total of 227 sera were tested in this study, including 84 samples from patients with APS, 104 samples from patients with non-APS diseases as disease controls, and 39 healthy controls. Serum IgG/IgM/IgA aCL and IgG/IgM/IgA aβ2GP1 were determined by both ELISA (QUANTA Lite® ELISA) and CIA (QUANTA Flash® assays).

Significant quantitative correlations were identified between ELISA and CIA in IgG/IgM/IgA aCL and IgG/IgM/IgA aβ2GP1 autoantibodies detection (P < 0.001), with the rho value ranging from 0.51 to 0.87. In addition, ELISA and CIA demonstrated good qualitative agreements in IgG/IgM/IgA aCL and IgG/IgM/IgA aβ2GP1 autoantibodies determination with kappa coefficient ranged from 0.52 to 0.77. In contrast, ELISA and CIA showed a moderate qualitative agreement in IgG aβ2GP1 detection with a kappa value of 0.2. Notably, significantly higher IgG aβ2GP1 positive sera were detected by CIA, compared to those detected by ELISA in both primary APS (52.9% vs. 8.8%) and APS associated to other diseases sera (70.0% vs. 8.0%). For diagnosis of APS, IgG aβ2GP1 detection by CIA (IgG aβ2GP1 CIA) demonstrated the highest sensitivity (63.1%), followed by IgG aCL CIA (48.8%). More importantly, IgG aβ2GP1 CIA demonstrated the highest ability to predict the thrombotic events in patients with APS, with an OR of 3 (95% CI: 1.1–7.9).

Our data suggest that this novel CIA assay had good performance in detecting aCL and aβ2GP1 antibodies, especially in the detection of IgG aβ2GP1 antibodies. Our findings could shed insight on the application of CIA in the laboratory diagnosis of APS in China.

INTRODUCTION

Antiphospholipid syndrome (APS) is a heterogeneous group of autoimmune disease characterized by recurrent arterial/venous thrombosis, and/or pregnancy morbidity, as well as the presence of antiphospholipid (aPL) antibodies. Primary APS (PAPS) is defined by no evidence of any underlying systemic autoimmune disorder, while APS associated to other diseases is associated with other systemic autoimmune syndromes, especially with systemic lupus erythematosus (SLE).1

As aPLs being a hallmark feature of APS, detection of aPLs represents the first-line approach for diagnosis of APS. According to 2006 updated consensus criteria of APS, the diagnosis of APS requires the persistent presence of at least one of the following aPLs, including lupus anticoagulant (LA), IgG and/or IgM anti-cardiolipin (aCL), and IgG and/or IgM anti-beta2 glycoprotein 1 (aβ2GP1) antibodies.1 2 IgA aCL and IgA aβ2GP1 antibodies are not currently included in the laboratory criteria for APS, but are suggested as “noncriteria” antibodies for seronegative patients with clinical suspicion of APS.23

Of note, the diagnosis of APS relies predominantly on laboratory findings, as characteristic clinical features of thrombosis and pregnancy morbidity also occur in many other diseases. In addition, these laboratory results are critical for predicting and stratifying the risks to develop the clinical manifestations of the syndrome. Unfortunately, the routinely used assays in clinical settings, particularly enzyme-linked immunosorbent assay (ELISA), lack standardized kits, resulting in substantial variations in the antibody positivity between different laboratories.4–6
Recently, the chemiluminescence technology has been applied for autoantibody testing. Several studies indicated that this novel assay had similar performance to commercial ELISAs and had a good agreement of results among laboratories regarding the detection of IgG/IgM aCL and IgG/IgM aβ2GP1 autoantibodies, suggesting that the chemiluminescence assay (CIA) could be a promising tool to improve the reproducibility and reduce interlaboratory variations. However, those studies have been performed in heterogeneous groups of patients in terms of different ethnic/geographic background, and most of these studies compared HemosIL® AcuStar CIA system or Zenit RA CIA system with either homemade ELISA or ELISA kit from another manufacturer.

With the introduction of QUANTA Flash® system, it is possible to compare the CIA system with ELISA kit from the same manufacturer. In addition, as CIA being a promising viable alternative, it is of paramount importance to evaluate this novel fully automated assay in aCL and aβ2GP1 autoantibodies detection in Chinese patients with APS. In the present study, we evaluated the analytical and clinical performance of a novel CIA assay (QUANTA Flash® assays) in the detection of IgG/IgM/IgA aCL and IgG/IgM/IgA aβ2GP1 antibodies and to compare it with commercial ELISA kits from the same manufacturer.

MATERIALS AND METHODS

Sera
A total of 227 sera were tested in this study, including 84 samples from patients with APS, 104 samples from patients with non-APS diseases as disease controls (non-APS), and 39 healthy controls (HC). The APS samples included 34 samples from patients with PAPS and 50 samples from patients with APS associated to other diseases. The non-APS samples included 30 samples from patients with non-APS diseases as disease controls (non-APS), 32 samples from patients with non-APS pregnancy-related morbidity (PRM), and 42 samples from patients with SLE. HC included subjects without any signs of infection or inflammation or other significant illnesses. The diagnosis of APS was determined according to the Sydney revised Sapporo guidelines. Specifically, subjects were diagnosed with APS based on a combination of one positive clinical criterion and one positive laboratory criterion (L.A. aCL or aβ2G1 antibodies determined by ELISA) on 2 different occasions separated by 12 weeks. The demographics and clinical characteristics of all subjects are shown in Table 1. All of samples were tested for LA. Study protocols were reviewed and approved by the Ethical Committee of Peking Union Medical College Hospital (PUMCH) and informed consents were obtained from all participants. All sera were stored at -20°C until analysis.

Serum Antibodies Determination
Sera aCL autoantibodies (IgG, IgM, and IgA) and aβ2GP1 (IgG, IgM, and IgA) were determined by both ELISA (QUANTA Lite® ELISAs, INOVA Diagnostic, Inc., San Diego, CA) and CIA (QUANTA Flash® assays, INOVA Diagnostic, Inc.) according to the manufacturer’s instructions. The QUANTA Flash® assays were performed on BIO-FLASH® instrument (Biokit S. A., Barcelona, Spain). The principle of the QUANTA Flash® assay system was previously described by Mahler et al. and Bentow et al. The cut-off values for positivity were set based on the recommendations by the manufacturer.

Statistical Analysis
SPSS 20.0 statistical software package (SPSS, Inc., Chicago, IL) and Prism 5.02 (GraphPad Software, San Diego, CA) were utilized for all statistical tests. Cohen kappa agreement test and Spearman correlation test were performed to analyze the qualitative and quantitative agreement between ELISA and CIA. Serial receiver-operating characteristic (ROC) curves were used to calculate the area under the ROC (AUC) for defining optimal cut-off values and analyzing the performance of different assays. Average linkage clustering by Heml 1.0 Heatmap Illustrator (The CUCKOO Workgroup, Hefei, Anhui, China) was used for cluster analysis. Hierarchical clustering was utilized to illustrate the relationship between different assays and to display the reactivity patterns of the patients. P values of less than 0.05 were considered statistical significant.

RESULTS

Clinical Characteristics
Clinical characteristics and laboratory findings of all subjects are listed in Table 1. Specifically, the incidence of arterial thrombosis in patients with PAPS, APS associated to other diseases, non-APS thrombosis, non-APS PRM, and SLE were 26.5%, 36.0%, 16.7%, 0, and 2.3%, respectively. The presence of venous thrombosis in patients with PAPS, APS associated to other diseases, non-APS thrombosis, non-APS PRM, and SLE were 41.2%, 52.0%, 86.7%, 3.0%, and 0, respectively. For calculation of the incidence of obstetric complications, we excluded male patients and nonmarried female patients. Thus, the calibrated incidence of obstetric complications in patients with APS, APS associated to other diseases, non-APS thrombosis, non-APS PRM, and SLE were 50.0%, 53.1%, 0%, 100%, and 0, respectively. LA was detected in 73.5% of PAPS patients, 80% of patients with APS associated to other diseases, 6.7% of patients with non-APS thrombosis, 3% of patients with non-APS PRM, and 11.9% of SLE patients.

aCL (IgG, IgM, and IgA) and aβ2GP1 (IgG, IgM, and IgA) Autoantibodies Detection by ELISA and CIA Assays
Table 1 shows the results of IgG/IgM/IgA aCL and IgG/IgM/IgA aβ2GP1 autoantibodies detection by ELISA and CIA from all tested sera. Except for IgM/IgA aβ2GP1 autoantibodies, all HC samples were negative by both assays. Similar percentages of positive results for IgG/IgM/IgA aCL and IgM/IgA aβ2GP1 autoantibodies were found in both assays. However, significantly higher IgG aβ2GP1 positive sera were detected by CIA, compared to those detected by ELISA in both PAPS (52.9% vs. 8.8%, P < 0.001) and APS associated to other diseases sera (70.0% vs. 8.0%, P < 0.001). IgA aCL and IgA aβ2GP1 autoantibodies have been considered as ‘non-criteria’ antibodies for seronegative patients with clinical suspicion of APS. Importantly, both IgA aCL and IgA aβ2GP1 autoantibodies detected by either assay were significantly higher in patients with APS than those in non-APS disease controls or HC (Table 1).

Qualitative Agreements and Quantitative Agreements Between ELISA and CIA Assays in aCL (IgG, IgM, and IgA) and aβ2GP1 (IgG, IgM, and IgA) Autoantibodies Determination
 Generally, ELISA and CIA demonstrated good overall agreements (>90%) in IgG/IgM/IgA aCL and IgM/IgA
TABLE 1. Demographic Characteristics and Antibody Profiles of APS Patients and Controls

|                                      | Primary APS (n = 34) | APS Associated to Other Diseases (n = 50) | Non-APS Thrombosis (n = 30) | Non-APS PRM (n = 32) | SLE (n = 42) | Health Controls (n = 39) |

**Clinical Performance Characteristics of ELISA and CIA Assays in aCL (IgG, IgM, and IgA) and aβ2GP1 (IgG, IgM, and IgA) Determination**

Assay performance characteristics for detection of IgG/IgM/IgA aCL and IgG/IgM/IgA aβ2GP1 autoantibodies were evaluated on both ELISA and CIA assays, and the results are summarized in Table 3. For diagnosis of APS, IgG aβ2GP1 detection by CIA (IgG aβ2GP1 CIA) demonstrated the highest sensitivity (63.1%), followed by IgG aCL CIA (48.8%), IgG aCL ELISA (36.9%), IgA aβ2GP1 ELISA (22.6%), and IgA aCL CIA (22.6%). Interestingly, IgG aβ2GP1 ELISA exhibited the lowest sensitivity (8.3%). Of note, the highest sensitivity observed in IgG aβ2GP1 CIA did not result in loss of specificity (93.7%) (Table 3). In addition, IgA aCL ELISA showed the highest positive predictive value (100%), and IgG aβ2GP1 CIA showed the highest negative predictive value (81.2%) (Table 3).
ROC analysis was performed to evaluate the discrimination power of ELISA and CIA for distinguishing patients with APS and controls. IgG αβ2GP1 CIA exhibited the best discrimination power with the area under the curves (AUC) of 0.86, followed by IgG aCL CIA (AUC of 0.85) and IgM αβ2GP1 CIA (AUC of 0.78) (Figure 2 and Table 3). Interestingly, IgM aCL ELISA, IgA aCL ELISA and IgG αβ2GP1 ELISA showed poor discrimination power with the AUC of 0.57, 0.57, and 0.58, respectively (Figure 2 and Table 3).

The odds ratios (OR) were calculated to evaluate the performance of each autoantibody tested by either ELISA or CIA in prediction of APS. Interestingly, all of the autoantibodies tested by both ELISA and CIA showed high ORs for predicting APS, ranging from 3.8 in IgA αβ2GP1 ELISA to 44.5 in IgG aCL CIA. Importantly, IgG αβ2GP1 CIA demonstrated the highest ability to predict the thrombotic events in patients with APS, with an OR of 3 (95% CI: 1.1–7.9) (Table 3). However, all the autoantibodies detected by either ELISA or CIA had little power to predict the obstetric risks (Table 3).

Cluster Analysis

To further illustrate the distribution of each autoantibody tested by either ELISA or CIA in patients with APS and controls, and to illustrate the relationships among these autoantibodies, a supervised cluster analysis with a dendrogram was performed. The cluster analysis indicates that the majority of PAPS and patients with APS associated to other diseases were positive for IgG αβ2GP1 CIA and IgG aCL CIA (Figure 3). Some of the controls also showed positive results in some autoantibodies by different assays. In addition, IgG aCL CIA clustered were found closer to IgG αβ2GP1 CIA than to IgG aCL ELISA (Figure 3). More importantly, the dendrogram shows that IgG αβ2GP1 CIA and IgG aCL CIA clusters, and to a less extent, IgG aCL ELISA

### Table 2. Qualitative Agreements Between ELISA and CIA Assays in αCL (IgG, IgM, and IgA) and αβ2GP1 (IgG, IgM, and IgA) Detection

|               | Overall Agreement (95% CI) | Positive Agreement (95% CI) | Negative Agreement (95% CI) | Kappa (95% CI) |
|---------------|-----------------------------|-----------------------------|-----------------------------|----------------|
| aCL IgA       | 94.3 (91.2–96.9)            | 40.9 (22.7–59.1)            | 94 (90.8–96.8)              | 0.55 (0.31–0.76) |
| aCL IgG       | 93.4 (89.9–96.5)            | 67.4 (52.2–80.4)            | 92.3 (88.8–95.9)            | 0.77 (0.64–0.87) |
| aCL IgM       | 95.6 (93.0–97.8)            | 54.5 (31.9–72.7)            | 95.3 (92.6–97.7)            | 0.68 (0.47–0.85) |
| αβ2GP1 IgA    | 91.2 (87.2–94.7)            | 41.9 (24.2–59.6)            | 90.7 (86.7–94.6)            | 0.52 (0.32–0.69) |
| αβ2GP1 IgG    | 76.7 (71.4–82.8)            | 14.8 (5.8–23.7)             | 75.7 (70.0–81.4)            | 0.20 (0.09–0.32) |
| αβ2GP1 IgM    | 96.9 (94.7–99.1)            | 56.3 (31.1–81.4)            | 96.8 (94.4–99.1)            | 0.71 (0.46–0.88) |

αCL = anticardiolipin antibody; αβ2GP1 = anti-β2 glycoprotein 1 antibody; CIA = chemiluminescence assay; ELISA = enzyme-linked immunosorbent assay

Qualitative agreements are given in percent, followed by kappa statistics (95% confidence intervals are provided in the parentheses).

### Figure 1.

Quantitative correlation between ELISA and CIA. Correlations between ELISA and CIA for IgA αCL (A), IgG αCL (B), IgM αCL (C), IgA αβ2GP1 (D), IgG αβ2GP1 (E), and IgM αβ2GP1 (F) antibodies detection are shown. Quantitative correlation between the ELISA and CIA for each individual antibody detection was calculated by Spearman correlation test. αβ2GP1 = anti-β2 glycoprotein 1, αCL = anticardiolipin, CIA = chemiluminescence assay.

DISCUSSION

The major findings in this study include: CIA strikingly increased the sensitivity in detection of IgG \( \beta_2 \)GP1 antibody without loss of specificity in patients with APS, compared with the results by ELISA; IgG \( \beta_2 \)GP1 detected by CIA demonstrated the ability to predict the thrombotic events in patients with APS, while IgG \( \beta_2 \)GP1 detected by ELISA or other antibodies detected by either ELISA or CIA showed poor ability in predicting the thrombotic risks; ELISA and CIA exhibited good overall qualitative agreements (>90%) in IgG/IgM/IgA aCL and IgM/IgA \( \beta_2 \)GP1 autoantibodies detection, while they only showed a moderate overall agreement (76.7%) in IgG \( \beta_2 \)GP1 detection; ELISA and CIA assays demonstrated significant quantitative correlations in IgG/IgM/IgA aCL and IgG/IgM/IgA \( \beta_2 \)GP1 autoantibodies detection. Our findings supported that CIA could serve as a promising viable alternative for ELISA in the detection of aCL and \( \beta_2 \)GP1 autoantibodies, especially in the detection of IgG \( \beta_2 \)GP1 autoantibody.

We found that CIA strikingly increased the sensitivity in detection of IgG \( \beta_2 \)GP1 antibodies compared with the results by ELISA. Importantly, the increased sensitivity of IgG \( \beta_2 \)GP1 by CIA did not sacrifice the specificity, PPV and NPV values. Several factors may contribute to the improved sensitivity by CIA, such as differences in detection system and antigens, as CIA utilized the full-length recombinant \( \beta_2 \)GP1 expressed in the insect cells as antigen in BIO-FLASH instrument. Moerloose et al.\(^\text{12}\) reported that IgG \( \beta_2 \)GP1 detected by CIA and IgG \( \beta_2 \)GP1 detected by ELISA had a comparable sensitivity in APS patients from Spain using the same CIA and ELISA systems, although a trend of higher sensitivity in CIA was observed. Interestingly, the sensitivity of IgG \( \beta_2 \)GP1 detected by CIA was higher in our study compared to that in Mondejar’s study,\(^\text{10}\) although the sensitivity of IgG \( \beta_2 \)GP1 detected by ELISA was much lower.

Despite widespread use of ELISA for detection of aCL and \( \beta_2 \)GP1 autoantibodies in clinical settings, several limitations, such as low reproducibility, substantial interlaboratory variations, challenged the role of ELISA in accurately evaluating the risks of developing APS-related complications.\(^\text{5,18}\) \( \beta_2 \)GP1 autoantibodies have been recognized as the main pathogenic subset in aPLs, especially with thrombosis events.\(^\text{12,17}\) However, we did not observe any association between IgG \( \beta_2 \)GP1 autoantibodies detected by ELISA with thrombosis events. In contrast, we did identify an association between IgG \( \beta_2 \)GP1 autoantibodies and thrombosis events using the CIA assay. Interestingly, Moerloose et al.\(^\text{12}\) reported that IgG \( \beta_2 \)GP1 determined by both ELISA (QUANTA Lite INOVA) and CIA (HemosIL\(^\text{16}\) AcuStar) significantly correlated with thrombosis events in patients with APS from Europe. As we used the same ELISA kit, the discrepancies may be due to different ethnic/geographic backgrounds or due to substantial interlaboratory variations in ELISA testing, as mentioned earlier.

Our results revealed good qualitative and quantitative agreements between CIA and ELISA in IgG/IgM aCL and IgM \( \beta_2 \)GP1 autoantibodies determinations. In IgG aCL detection, CIA and ELISA showed good overall, positive and negative agreements of 93.4%, 67.4%, and 92.3%, respectively, which is similar to what has been previously described by Mondejar et al.\(^\text{10}\) (90.1%, 68.4%, and 95.1%, respectively). However, for IgM aCL and IgM \( \beta_2 \)GP1 antibodies detection, the overall and positive agreements between CIA and ELISA in our study were higher.
than what they have reported.\textsuperscript{10} Chung et al\textsuperscript{13} compared Hemo-
siL\textsuperscript{10}. AcuStar CIA system with QUANTA Lite ELISA, and found an overall agreement of 86.2% in IgM aCL detection, which was lower than what we have found (95.6%). However, for IgM β2GP1 detection, they found an overall agreement of 93.6%, which is similar to what we reported (96.9%).\textsuperscript{13}

The 2006 Sydney criteria for APS suggest IgA aCL and IgA β2GP1 antibodies as “non-criteria” antibodies for seronegative patients with clinical suspicion of APS.\textsuperscript{2} We also evaluated the clinical performance of CIA and ELISA in the determination of levels of IgA aCL and IgA β2GP1 antibodies. Our data demonstrated that CIA and ELISA had good overall qualitative agreements and good quantitative agreements, as determined by Cohen kappa agreement test and Spearman correlation test, respectively. Importantly, we found that both IgA aCL and IgA β2GP1 antibodies either detected by CIA or by ELISA in patients with APS were strikingly higher than those in non-APS disease controls or health controls, supporting the 2006 Sydney criteria that IgA aCL and IgA β2GP1 antibodies could contribute to the diagnosis of APS. However, we did not identify any associations either between IgA aCL and thrombosis events/obstetric complications or between IgA β2GP1 and thrombosis events/obstetric complications, which is different from the results from Despierres et al.\textsuperscript{19} Despierres et al\textsuperscript{19} found that IgA β2GP1 antibodies were significantly correlated with thrombosis events, but not obstetric complications.

It should be noted, however, that several limitations exist in our study. Patients with APS were diagnosed based on the 2006 updated consensus criteria, which requires presence of at least one of the LA, aCL, and β2GP1 autoantibodies. It has been proposed that seronegative APS, which refers as patients with clinical manifestations indicative of APS but with persistently negative results in the routinely used assays to detect the LA, aCL, and β2GP1 autoantibodies, does exist.\textsuperscript{20} Thus, we may ignore these seronegative APS patients in our study. Further studies on those patients are needed.

In addition, our findings need to be confirmed in other independent study, especially the greatly improved sensitivity of the IgG β2GP1 assay by CIA as compared to the conventional ELISA. This information would be particularly important, as ELISA is currently widely used in Chinese hospitals in the detection of aPLs.

In summary, our data suggest that this novel CIA assay had good performance characteristics in detecting aCL and β2GP1 antibodies, especially in the detection of IgG β2GP1 antibodies. Of particular interest is the finding that CIA had a better prediction power of thrombosis events. In addition, considering the advantage of being fully automated, CIA allows for a decrease in interlaboratory variability and an increase in reproducibility. Our findings could shed insight on the introduction and application of CIA in the laboratory diagnosis of APS in Chinese hospitals.
