Guidelines to identify abnormalities after childhood urinary tract infections: a prospective audit

Malcolm G Coulthard, Heather J Lambert, Susan J Vernon, Elizabeth W Hunter, Michael J Keir

ABSTRACT

Objective To compare the childhood urinary tract infection (UTI) guidelines from the Royal College of Physicians (RCP) in 1991 and from National Institute of Health and Care Excellence (NICE) (CG54) in 2007 by measuring their efficiency at detecting urinary tract abnormalities.

Design Children with UTIs within the Newcastle Primary Care Trust (population 70 800 children) were referred and imaged according to the RCP guidelines during 2008, and these were compared to the activity that would have been undertaken if we had implemented the CG54 guidelines, including following them through 2011 to identify those with recurrent UTIs.

Main outcome measures The numbers of children imaged, the imaging burden and efficiency, and urinary tract abnormalities detected by each guideline.

Results Fewer children would have been imaged by CG54 than RCP (150 vs 427), but its sensitivity was lower, at 44% for detecting scarring, 10% for identifying vesicoureteric reflux and 40% for other abnormalities. Overall, it would have only detected one-quarter of the abnormal cases (8 vs 32) and would have missed five of nine children with scarring, including three with multiple lesions and one with renal impairment. Imposing an age restriction of <8 years to the RCP guidelines would reduce its screening rate by 20% and still detect 90% of the abnormalities.

Interpretation The CG54 guidelines do not alter the imaging efficiency compared to the RCP guidelines, but they are considerably less sensitive.

INTRODUCTION

From 1991, most UK paediatricians managed urinary tract infections (UTIs) according to recommendations from the Royal College of Physicians (RCP), but these generate a high imaging burden (table 1) and were not felt to substantially improve the outcomes for children. Thus, the National Institute of Health and Care Excellence (NICE) drew up new guidelines (CG54) in 2007 which were designed to reduce the imaging burden by investigating higher risk children, using the selection criteria summarised in table 2. The Newcastle GPs and the Newcastle upon Tyne Hospitals NICE Guideline Committee undertook a preimplementation audit of CG54 against their existing RCP-based guidelines because CG54 had not been trialled.

PATIENTS AND METHODS

In Newcastle, GPs serving a population of 70 800 children aged <16 years refer those who develop a proven UTI (defined as ≥10⁷/mL colonies of a single uropathogen cultured from their urine) to a nurse-led direct-access service, where they are investigated further, a nurse-led direct-access service, and the Newcastle Children’s Hospital Imaging Department took the following steps: (1) perform ultrasound and a DMSA scan, and (2) if these are normal, arrange a standard voiding cystourethrogram (MCUG) or a MAG3 indirect cystogram from the age of about 3.5 years.

Table 1 The imaging recommended for screening children following a UTI, according to the Newcastle guidelines, modified from the 1991 RCP publication

| Age categories (years) | Clinical features | Ultrasound | DMSA | MCUG |
|------------------------|------------------|------------|------|------|
| <1                     | First UTI        | +          | +    | +    |
| 1–4                    | First UTI        | +          | +    | +    |
| >4                     | First UTI Recurrence | +    | +    | +    |

*For a child aged 1–4 years with a recurrent UTI and a previously normal MCUG, no investigations are needed. If no prior MCUG had been done, the options include having one then, or managing the child as if they were known to have VUR, and undertaking a MAG3 indirect cystogram from the age of about 3.5 years. DMSA, dimercaptosuccinic acid; MCUG, micturating cystourethrogram; RCP, Royal College of Physicians; UTI, urinary tract infection; VUR, vesicoureteric reflux.
imaged using a protocol based upon the RPC guidelines. All children referred appropriately have an ultrasound and delayed dimercaptosuccinic acid (DMSA) scan after their first UTI (table 1). Infants aged <1 year also have a micturating cystogram to look for vesicoureteric reflux (VUR), as may children aged <4 years with recurrences. Children who have normal DMSA scans are not considered to be at risk of developing scars with a future UTI if they are over the age of 4 years or if they are younger but have been shown not to have VUR.

The GP referral information routinely collected by the direct-access service makes it simple to identify how each child would have been managed according to the CG54 guidelines, where the algorithm to decide upon renal tract imaging depends upon age, the presence of atypical features and recurrent infections (table 2). We audited all children referred during 2008 and followed them up for between 3 and 4 years, until the end of 2011 to identify cases with recurrent infections. This audit was designed to evaluate a potential service development, so did not require ethics committee approval. We analysed the results in four clinically appropriate age bands: <1, 1–3, 3–8 and 8–16 years.

**RESULTS**

Five hundred and thirty-two children were referred for a proven UTI during 2008, but of these 53 were not considered to be genuine infections on culture criteria, and 29 patients did not
attend any appointments (figure 1). Of the 450 children (80.0% girls) with a proven UTI who participated in the investigation programme, 427 (94.9%) were imaged according to the RCP-based protocol because it was their first recognised UTI, while 23 who had been investigated previously were not retested because their earlier imaging was considered to exclude the risk of future scarring; 150 children would have been imaged according to the CG54 guidelines. Among these, 24 (16%) were aged <6 months with a single typical UTI, 58 (39%) met the CG54 'atypical' criteria (all by culturing non-\textit{Escherichia coli} uropathogens) and 66 (44%) had a recurrent UTI either at presentation (23) or before the end of 2011. Thirty children had atypical and recurrent UTIs.

The imaging outcomes and efficiency (number of children tested per abnormality detected) are shown in table 3 for both guidelines. The efficiencies for each test and for the overall imaging strategy were similar for both guidelines (p ≥ 0.46 for all, Fisher’s exact test), but CG54 would only have resulted in 35.1% of the children being tested. The RCP imaging schedule detected nine children with DMSA abnormalities consistent with scarring (6 with multiple lesions, 1 with a reduced kidney function), while CG54 would have detected 4 (3 multiple, none with renal impairment) and missed 5 (figure 2). The RCP-based guidelines detected VUR in 34 ureters in 21 children (grade ≥ 2 in 90%), while CG54 would have been identified bilateral grade 2 reflux in 2 babies with non-\textit{E coli} UTIs. Ultrasound detected the fewest number of abnormalities, and only identified one child (with multiple renal cysts) whose other imaging was normal.

The specificity values of the CG54 tests to identify scarring, VUR or other abnormalities were all 1 compared to the RCP guideline results because they did not identify any extra positive findings. However, the sensitivities were generally considerably lower (table 4).

**DISCUSSION**

NICE’s CG54 case selection criteria did not change the efficiency of their childhood UTI guidelines compared to the RCP-based ones. Following the CG54 guideline would have reduced the numbers of children tested by two-thirds, but would have missed over half of those who had scars, including those with multiple lesions. When following either protocol,
approximately one-quarter of the cystograms undertaken demonstrated reflux. The value of detecting VUR is controversial, but we have identified a way in which this information may assist in preventing kidney scarring.4

If we had used the RCP-based guidelines but had restricted their routine use to children aged <8 years, that would have reduced the number of children imaged by about 20%, but would still have identified 90% of the abnormal cases, including eight of the nine children with scars. Reducing the limit to <4 years would have reduced the number of children imaged by about 50%, would still have identified about 80% of the abnormal cases, but would have missed nearly half (4/9) of the children with scars, of whom three had multiple scarring.

Table 4  Sensitivity values for CG54 compared to using the RCP guideline, up to 8 years

| Diagnosis       | All <1 year | 1–8 years |
|-----------------|-------------|-----------|
| Scars           | 0.44        | 0.29      |
| VUR             | 0.10        | 0.00      |
| Other findings  | 0.40        | 0.00      |

*Note that this value represents just 1 case identified.

RCP, Royal College of Physicians; VUR, vesicoureteric reflux.
