Aflatoxin B₁ residues in human livers and their relationship with markers of hepatic carcinogenesis in São Paulo, Brazil

Leandra N.Z. Ramalho, Livia D. Porta, Roice E. Rosim, Tânia Petta, Marlei J. Augusto, Deisy M. Silva, Fernando S. Ramalho, Carlos A.F. Oliveira

Keywords: AFB₁, Hepatocellular carcinoma, Cirrhosis, Markers

1. Introduction

Aflatoxins are carcinogenic secondary metabolites produced by fungi in the genus Aspergillus, especially the species A. flavus, A. parasiticus, and A. nomius, which naturally grow in food products (Murphy et al.). There are 20 known similar compounds called aflatoxins, although the main types of interest in terms of health are B₁, B₂, G₁, and G₂ [1]. Aflatoxin B₁ (AFB₁), besides being the most frequently one found in plant substrates, is the one with the highest toxigenic power [2]. The toxin is ingested with contaminated food, mainly foodstuffs that undergo storage, such as peanuts, corn, beans, and rice. AFB₁ is genotoxic and is considered one of the most potent natural mutagenic agents. Involvement in liver carcinogenesis is the most important effect of aflatoxin chronic toxicity [3]. Brazilian regulations determine maximum levels of aflatoxins (sum of AFB₁, AFB₂, AFG₁, and AFG₂) ranging from 1 to 20 μg/kg [4] in several foodstuffs.

Aflatoxins are absorbed in the gastrointestinal tract and primarily biotransformed in the liver by means of microsomal enzymes from the cytochrome P450 mixed function oxidase system [5]. AFB₁ requires metabolic activation to show its toxic effects, and its carcinogenic form is the highly active electrophilic metabolite AFB₁-8,9-oxide or AFB₁-epoxide, which originates from the epoxidation of the vinyl-ether double bond found in the di-furan structure of AFB₁ molecule [6,7]. AFB₁ activated form quickly reacts with covalent bonds of macromolecules, such as cellular deoxyribonucleic acid (DNA), ribonucleic acid (RNA), as well as proteins [6]. The bond with DNA leads to the production of adducts with guanine in the N7 position at codon 249 of p53 tumor suppressor gene. Besides epoxidation, AFB₁ biotransformation includes hydroxylation originating aflatoxins M₁ (AFM₁), Q₁ (AFQ₁), and B₂α (AFB₂α), as well as O-demethylation, originating aflatoxin P₁ (AFP₁), which may undergo conjugation with glucuronic acid or sulfates, and is excreted in urine, bile, and feces [8]. Aflatoxicol (AFL) can also be formed by the reduction of AFB₁ by means of an NADPH-dependent cytoplasmic enzyme found in the soluble fraction of...
liver homogenates [9]. All these biotransformation products of AFB1 may remain in the form of residues in the liver, as observed in several species [10]. These residues are considered markers of toxin exposure in the diet.

Hepatocellular carcinoma (HCC) is the most frequent malignant neoplasm found in the liver, and the third most important cause of cancer deaths in the world. Greater occurrence of HCC is associated with the presence of chronic liver disease in up to 90% of the cases [11]. Africa and China have the greatest incidence of HCC compared with the rest of the world due to aflatoxin exposure, besides the known risk factors of western countries, such as viral hepatitis and alcoholism. In Brazil, HCC is now the 7th cause of cancer death. However, different from the pattern in the rest of the world, 42% of the HCC cases in Brazil do not show positive serology to viral hepatitis, and there are regional differences [12]. These differences may correspond to AFB1 exposure, taking into account the association between AFB1, HCC the induction of a specific mutation in p53 gene [13]. However, this relationship has not been investigated in Brazil, and there are no previous studies on the occurrence of AFB1 residues in human livers in this country.

Hepatocarcinogenesis seems to be a multifactorial process in which extrinsic stimuli induce gene changes in mature hepatocytes, leading to successive proliferation and death, and culminating in the production of monoclonal populations. Evidence suggests that hepatocarcinogenesis may begin with pre-neoplastic lesions, such as regenerative macronodules and hepatic nodules with low or high-grade dysplasia. Therefore, the accumulation of genetic changes and new mutations in pre-neoplastic lesions may probably cause HCC [14]. Mutations were identified in several critical genes involved in hepatocarcinogenesis, such as p73, p53, Rb, APC, DCC-1 (deleted in liver cancer), p16, GSTP1, PTEN, IGFI-2, BRCA2, SOCS2, Smad2 and Smad4, β-catenin, c-myc + c, and cyclin D1 [15,16]. The p53 may also be related with other tumor suppressing gene, Prohibitin (PB). PB may be found in the cytoplasm or nucleus, according to the pathological characteristics of the cell [17]. In the nucleus, PB seems to be essential in the regulation of cell processes such as apoptosis, proliferation, and gene transcription [18].

Besides p53, other pathogenic mechanisms that may cause HCC after aflatoxin exposure still need to be studied. Cyclins are a family of proteins that are directly involved in the regulation of the cell cycle [19]. Changes in cyclin activities in transformed cells contribute to the acceleration of the cell cycle, which may be due to the lack of control of pathways that regulate cyclin synthesis, or to mutations that lead to the loss of function in inhibiting proteins [20]. The pathway p16/cyclin D1/Rb (retinoblastoma) may be considered the major cell cycle regulator. There are also three important inhibitors of cell cycle progression belonging to the Cip/Kip family: p27kip1, p21waf1, and p57kip2. However, little is known about the interference of major chronic liver diseases, such as cirrhosis associated with viral hepatitis or alcoholism, in AFB1 biotransformation in the liver. The objective of the present study was to investigate the occurrence of residual AFB1 or its metabolites in hepatic biopsies from autopsy cases, and the association of these residues with mechanisms related to hepatocarcinogenesis.

2. Material and methods

2.1. Sampling procedures

A total of 58 human liver samples were collected from patients (46 males and 12 females) with HCC (n = 8), cirrhosis associated with viral hepatitis (VC, n = 20), cirrhosis associated with alcoholism (AC, n = 20), and normal livers (NL or controls, n = 10). These livers came from autopsies performed at the Division of Pathology of a University Hospital in Ribeirão Preto, Brazil, from 2011 to 2014. Post-mortem time for sample collection was around 6 h. Clinical data were obtained from patients’ records. Patients with evidence of human immunodeficiency virus infection, autoimmune or drug-induced hepatitis, endocrine disorders, or any other cause of liver disease were excluded from the study. The ethical guidelines from the Helsinki Declaration (1975) were followed in the study, and it also was approved by the Ethics Committee of the School of Medicine of the University of São Paulo at Ribeirão Preto (protocol no. 1611/2011). Each liver sample was subdivided in two parts: one was fixed in 10% buffered formalin for 48 h and then embedded in paraffin; and the other was placed in RNA stabilizing solution (RNAlater RNA Stabilization Reagent, Qiagen, Turnberry Lane, CA, EUA), frozen in liquid nitrogen, and stored at −80 °C. Paraffin-embedded sections were stained with hematoxylin and eosin (H&E) for confirmation of the original diagnosis.

2.2. Determination of aflatoxin B1 and metabolites

Liver samples stored at ~80 °C were thawed at room temperature. Aflatoxin was extracted according to Chiavaro et al. [21] and purified through immunoaffinity columns (Affiload WB®, Vicam, Watertown, MA, USA). Briefly, 1.0 g of liver sample was ground in a mortar and the resulting slurry was transferred to a 5-mL cryotube containing 4.0 mL of methanol/water (80:20, v/v) and 10 μL of internal standard (IS) working solution (described in the end of this section). The mixture was sonicated for 10 min, vortexed for 30 s and allowed to stand overnight at 7–10 °C. After that period, vortexing and sonication were repeated, and samples centrifuged (Sorvall® RC 3B Plus) at 3600 × G for 10 min. An aliquot (4 mL) of the supernatant was diluted with 25 mL of PBS and passed through the immunoaffinity cleanup column. The column was washed with 20 mL of PBS and then 2 mL of deionized water. After the washing steps, aflatoxins were eluted with 2 mL of methanol, dried, and reconstituted in 500 μL of acetonitrile/water (1:1, v/v). This solution was filtered (PTFE, 0.22 mm, Millex, Millipore Corp) and transferred to an amber glass vial.

Residual levels of AFB1, AFM1, AFQ1, AFL, and AFL were determined by ultra-performance liquid chromatography coupled to tandem mass spectrometry (UPLC-MS/MS using [13C17]-AFB1 (Sigma, St. Louis, MO, USA) and [13C17]-AFM1 (Biopure, Romer Labs, Tullin, Austria) as internal standards. To prepare the calibration lines for the quantification assay, a standard working solution with a mixture of all standard aflatoxins (AFB1, AFM1, AFQ1, AFL, AFB2, and AFL) at 10 μg/L each) were dissolved in acetonitrile/water (1:1, v/v) and diluted to the final concentrations of 1.0, 0.750, 0.5, 0.1, 0.05, and 0.01 ng/mL. An additional calibration line was constructed for 10, 8, 4, and 2 ng/mL AFB1 by means of dilution of an individual AFB1 standard solution (10 ng/mL). The IS working solution (25 ng/mL [13C17]-AFB1 and 100 ng/mL [13C17]-AFM1) was prepared in acetonitrile/water (1:1, v/v) and added to all composite standards at a final concentration of 0.5 ng/mL and 2.0 ng/mL, respectively. The curves were determined by plotting the ratio of the standard peak area to the IS peak area against the concentration of the calibration standards. For aflatoxin quantification, the peak area ratios of the analytes to the IS were calculated, and concentration was determined by the corresponding calibration line. LOD and LOQ values were calculated based on signal-to-noise ratios of 3:1 and 10:1, respectively, of peaks corresponding to the confirmatory Multi Reaction Monitoring (MRM) transitions.

Final extracts were injected into a Waters Acquity I-Class UPLC system (Waters, Milford, MA, USA) coupled to a Xevo TQ-S mass spectrometer (Waters, Milford, MA, USA). The column (BEH C18, 2.1 × 50 mm, 1.7 μm) was kept at 40 °C during the analyses, and samples were maintained at 15 °C. The injection volume of extracted samples and standards was 10 μL. The mobile phase was composed by water (eluent A) and acetonitrile (eluent B), both containing 0.1% of formic acid. After an initial period of 0.5 min at 95% eluent A, the percentage of eluent B was linearly raised to 25% over 4.5 min (5.0 min). Then, eluent B was increased to 90% over 0.5 min, followed by a hold time of 0.25 min (5.5 min). After that, the percentage of eluent B was reduced to 5% over 0.5 min (6.0 min), and the column re-equilibrated to the initial conditions for 0.5 min. Total chromatographic run time was 6.5 min, and the flow rate was maintained at 0.5 mL/min.
were separated by centrifugation at 700g for 10 min. Nucleic acids were hydrolyzed with 100 μL of chloric acid 0.1 M for 16 h. The hydrolysate was filtered in a 0.45 μm filter, and AFB1-N7-guanine was extracted with an equal volume of ethyl acetate. After agitation, the organic phase was transferred to an amber glass vial, dried, and re-suspended in 500 μL methanol/water (1:1, v/v) for LC-MS/MS analysis.

The AFB1-N7-guanine standard (Toronto Research Canada, Toronto, ON, Canada) was diluted in methanol:1% acetic acid in water (50:50, v/v) and stored at −20 °C. A 5-point calibration curve was prepared in methanol/water (1:1, v/v) at the range from 0.2 to 2.5 ng/mL by means of serial dilutions of the AFB1-N7-guanine standard solution (10 ng/mL). The [13C17]-AFB1 IS peak area was used to correct the concentration of the analyte determined by means of the corresponding calibration line. The final extracts were injected in the same UPLC system coupled to a Xevo TQ-S mass spectrometer (Waters, Milford, MA, USA) as described in Section 2.2, keeping the same temperature conditions, injection volumes, elution gradients and flow rate. Total chromatographic run time was 3.0 min, and the retention time for AFB1-N7-guanine was 1.42 min. The mass spectrometer parameters were also set as described in Section 2.2. Quantification and confirmatory MRM transition for AFB1-N7-guanine were m/z 480.33 > 152.07 and 480.33 > 135.06, respectively.

2.4. Immuno-histochemical analyses

Liver sections were incubated with monoclonal primary antibodies specific for Rb, p16INK4D, β-catenin, cyclin D1, and p53 (Santa Cruz Biotechnology, Santa Cruz, CA, USA, dilution 1:100); p21WAF1/Cip1 and p27Kip1 (Dako, Carpinteria, CA, USA, dilution 1:100); and PB (Thermo Fisher Scientific Waltham, MA, USA, dilution 1:100). After that, a secondary antibody (Vectastain Elite ABC Kit, Universal, Vector Laboratories Inc.) was applied. Next, the slides were incubated with avidin-biotin-peroxidase complex (Vectastain Elite ABC Kit) and developed with 3,3-diaminobenzidinetetrahydrochloride (DAB) kit (Vector Laboratories Inc.) for 5 min. Slides were counterstained with Harris hematoxylin and mounted with Permount (Biomed, Foster City, CA, USA). As negative controls, all specimens were incubated without the primary antibodies under identical conditions. Percentages of Rb, p16INK4D, β-catenin, cyclin D1, p53, p21WAF1/Cip1, p27Kip1, and PB-positive cells in each case were obtained blindly and independently by two of the authors (LDP and LNR), in at least 10 representative high-power fields (40×). Concordance between the authors ranged 95%.

2.5. Gene expression analyses

Gene expression was analyzed by real time PCR (RT-PCR). Frozen liver samples were used to quantify gene expression of p53, p21WAF1/Cip1, Rb, cyclin D1, and PB. Tissue fragments were homogenized and subjected to analysis of total RNA expression using a specific kit (RNeasy Mini Kit, QIAGEN, CA, USA). During the procedure, complementary DNA was obtained by reverse transcription using a retro-transcription kit (Ready-To-Go You-Prime First-Strand Beads and pd(N) 6 Random Hexamer; Amersham Biosciences), beginning with 5 μg total RNA. Gene amplification with concurrent quantification was conducted by RT-PCR StepOnePlusTM (Applied Biosystems Inc., Foster City, CA, USA) using specific primers for p53, p21WAF1/Cip1, Rb, cyclin D1, PB, and GAPDH genes (Assays-on-Demand Gene Expression Products, Applied Biosystems), and a specific Taq Polymerase enzyme (TaqMan Universal PCR Master Mix, No AmpErase UNG - 2X, Applied Biosystems). All experiments were performed in duplicate, and the results were normalized to GAPDH mRNA expression.

2.6. Statistical analyses

The results on aflatoxin residues found in liver samples were used to distribute immuno-histochemical and gene expression data in two

* Transitions used for quantification.
** Transitions used for confirmation.

Retention times for AFB2b, AFQ1, AFM1, AFB1, AFP1, and AFB1 were 1.14, 1.16, 1.17, 1.24, 1.28 and 1.29 min, respectively. The mass spectrometer was operated in MRM mode using electrospray ionization in positive ion mode and the following conditions: capillary voltage: 0.75 kV; source temperature: 150 °C; desolvation temperature; 500 °C; cone gas flow: 800 L/h; and cone gas flow: 150 L/h. Quantification and confirmatory MRM transitions for aflatoxins and corresponding optimal mass spectrometric parameters used in the LC-MS/MS analysis are presented in Table 1. Data collection and processing was performed using software MassLynx version 4.1.
3.2. Aflatoxin B1 residues

Thirteen liver samples (22.4%, N = 58) were positive for residual AFB1, with levels ranging from 10.0 and 418.0 pg/g (mean: 76.6 ± 107.7 pg/g), as shown in Table 3. The percentage of liver samples showing AFB1 in individuals with HCC (n = 8), VC (n = 20) and AC (n = 20) was 37.5%, 15%, and 35.0%, respectively. Mean levels of AFB1 in the livers with HCC and VC were similar (63.0–64.0 pg/g); however, the concentration of the toxin in the livers with AC was greater (87.9 pg/g), with large standard deviation (158.1 pg/g) due to a sample that showed much higher levels than the others (418.0 pg/g) (Fig. 1). Control patients (NL, n = 10) without history of liver disease did not show residues of AFB1 or its metabolites in their livers. Furthermore, aflatoxin metabolites (AFM1, AFP1, AFQ1, AFB2, AFL) or AFB1-N7-guanine were not found in any of the samples analyzed. LOQ values were 10 pg/g (AFB1 and AFL), 25 pg/g (AFB2), and 50 pg/g (AFP1, AFQ1 and AFM1). Determined LOD values were 4 pg/g (AFB1 and AFL), 8 pg/g (AFB2), and 16 pg/g (AFP1, AFQ1, and AFM1). For AFB1-N7-guanine, LOQ and LOD values were 90 and 30 pg/g, respectively.

Table 2
Gender and age of the individuals autopsied in the Division of Pathology of an University Hospital in Ribeirão Preto, Brazil, from 2011 to 2014.

| Type of liver disorder | Gender | Age (years) | N | n | % | n | % | n | % |
|-----------------------|--------|-------------|---|---|----|---|----|---|----|
|                       | Male   | Female      | >50 | | 50 | | | | |
| HCC                   | 8      | 5           | 62.5 | 3 | 37.5 | 2 | 25.0 | 6 | 75.0 |
| VC                    | 20     | 16          | 80.0 | 4 | 20.0 | 5 | 25.0 | 15 | 75.0 |
| AC                    | 20     | 18          | 90.0 | 2 | 10.0 | 7 | 35.0 | 13 | 65.0 |
| NL (control)          | 10     | 7           | 70.0 | 3 | 30.0 | 2 | 20.0 | 8 | 80.0 |
| Total                 | 58     | 46          | 79.3 | 12 | 20.7 | 16 | 27.6 | 42 | 72.4 |

N: Number of individuals autopsied for each type of liver disorder.
HCC: Hepatocellular carcinoma.
VC: Cirrhosis associated with viral hepatitis.
AC: Cirrhosis associated with alcoholism.
NL: Normal liver.

Groups: AFB1 positive (AFB1+) and AFB1 negative (AFB1−). Data were analyzed using the GraphPad Prism software 4.0 (GraphPad Software, San Diego, CA, U.S.A.). All data are reported as means ± standard deviations. Statistical comparisons of the groups were performed by Kruskal-Wallis nonparametric one-way analysis of variance followed by Dunn’s posttest or Mann-Whitney test. Probability values less than 0.05 were considered statistically significant [24].

3. Results

3.1. Overview of clinical-pathological data

Table 2 shows the distribution of autopsied individuals according to the hepatic disorder, to gender and age. Most the patients were men (79.3%), older than 50 years of age (72.4%), and this proportion was the hepatic disorder, to gender and age. Most the patients were men

Table 3
Aflatoxin B1 residues in liver samples from autopsied individuals in São Paulo, Brazil.

| Type of liver disorder | N | n | (%) | Positive samples | Levels (pg/g) | Mean b | Variation |

3.2. Aflatoxin B1 residues

3.3. Immuno-histochemical parameters and aflatoxin B1 residues

Comparative immuno-labeling of p53, cyclin D1, p21, and p27 in AC AFB1+ and AFB1− liver samples was presented in Fig. 2. HCC, VC and AC AFB1+ groups presented higher labeling for p53 than HCC, VC and AC AFB1− groups. Only the AC AFB1− group showed p53 expression similar to the NL group; in all the other groups, p53 expression increased significantly. HCC, VC, and AC AFB1+ groups showed increased labeling for cyclin D1 compared with HCC, VC, and AC AFB1− groups, as well as with the NL group. HCC AFB1+ group presented higher labeling for p21 than the HCC AFB1− group. There was no significant difference between VC and AC AFB1+ groups, and VC and AC AFB1− groups. However, all the other groups showed higher p21 expression than normal livers. HCC AFB1− group presented higher labeling for p27 than the HCC AFB1+ group. There was no significant difference between VC and AC AFB1+ groups, and VC and AC AFB1− groups. Additionally, the expression of p27 was decreased in all groups in relation to the NL group.

Fig. 3 presents the immuno-labeling of p16, Rb, β-catenin, and PB in the liver samples. Immuno-expression for p16 was decreased in all groups with liver disease compared with normal livers. HCC, VC, and AC AFB1+ groups showed lower labeling for p16 than HCC, VC, and AC AFB1− groups. HCC, VC, and AC AFB1+ groups showed lower labeling for Rb than HCC, VC, and AC AFB1− groups. Rb expression was lower than the NL group in all HCC, VC, and AC groups. HCC and AC AFB1− groups presented higher labeling for β-catenin than HCC and AC AFB1− groups. There was no significant difference between the VC AFB1− groups and VC AFB1− groups. The β-catenin labeling was increased in all groups compared with normal livers. AC AFB1+ group had higher PB marking than AC AFB1− group. HCC and VC AFB1− groups did not show higher PB expression in relation to HCC and VC AFB1− groups. PB expression was higher than the NL group in all other groups.
3.4. Gene expression and aflatoxin B1 residues

There was no difference in p53 expression (Fig. 4) between HCC, VC and AC AFB1+ groups, and HCC, VC and AC AFB1− groups. HCC and AC AFB1+ groups presented higher expression of cyclin D1 than HCC and AC AFB1− groups. There was no significant difference between VC AFB1+ and VC AFB1− groups. VC and AC AFB1+ groups showed higher p21 expression than VC and AC AFB1− groups. There was no significant difference between the groups HCC AFB1+ and HCC AFB1−. AC AFB1+ presented lower Rb expression than AC AFB1− group. There was no difference in Rb expression between HCC and VC AFB1+ groups, and HCC and VC AFB1− groups. HCC and AC AFB1+ groups showed higher PB expression than HCC and AC AFB1− groups. There was no significant difference between the groups VC AFB1+ and VC AFB1−.

4. Discussion

In the present study, HCC, VC, and AC liver specimens from patients autopsied in São Paulo showed detectable levels of AFB1 residues. Previous studies demonstrated that, in general, levels of aflatoxin reported in foodstuffs commercialized in Brazil [25,26] complied with the limits determined by local regulations [4]. Studies on biomarkers of AFB1 exposure in urine [27,28] and serum [29] in individuals from the state of São Paulo corroborate these findings, as they indicated low exposure to the toxin in foodstuffs. However, data obtained in the present study suggest that exposure to AFB1 may be high in some population groups in Brazil. In this study, it was not possible to analyze the eating habits of the patients in order to assess the level of previous aflatoxin exposure. Experiments conducted with human subjects indicated that 95% of AFB1 and its metabolites are eliminated in urine within 24 h [30]. However, there are no estimates on the conversion ratios of AFB1 in the diet into AFB1 and/or other residual metabolites in human livers. This ratio varies widely in experimental studies carried out with laboratory and production animals. In pigs, the estimated value was 800:1 [10]. If this ratio is directly extrapolated to humans with the mean residual AFB1 level obtained in the present study (76.6 pg/g), mean levels of AFB1 in the diet of the patients would be about 60 μg/kg, corresponding to three times the maximum limit for aflatoxins (20 μg/kg) determined in Brazil [4].

The results for HCC are similar to previous data on the incidence of aflatoxins in livers of HCC patients in Czechoslovakia [31]. Furthermore, our data demonstrated that the patients were exposed to dietary aflatoxins, providing evidence that support the association between
aflatoxin exposure and the occurrence of HCC, for the first time in Brazil. However, the presence of AFB1 in cirrhotic livers (VC and AC) warrants concern about the potential contribution of dietary aflatoxin for the liver disease progression. These findings are in agreement with those described by [32], who observed that exposure to AFB1 increased the risk of cirrhosis and HCC in a dose-response manner among chronic carriers of hepatitis B virus. The absence of detectable metabolites of AFB1 (AFM1, AFP1, AFQ1, AFB2α, AFL) in liver samples was surprising, as several studies demonstrated that the accumulation of bio-transformation products of AFB1 in animal tissues preferentially takes place in the liver [23,33]. The AFB1-N7-guanine adduct was not detected in any liver sample, indicating that liver DNA was not affected at the time of sample collection, although there are no available studies on the rate of AFB1-DNA repair in the liver in humans or animal models. However, taking into account the genotoxic changes caused by AFB1 [6], it can be hypothesized that its residues in the liver would play an additional role in the pathogenic pathway linking cirrhosis and HCC.

Regarding the mechanisms involved in hepatocarcinogenesis, genes Rb and p16 act as tumor suppressing genes when cyclin D1 is activated as an oncogene. However, cyclin D1 high expression in HCC is variable, ranging from 6 to 76% [34,35]. The analysis of cyclin D1 aberrant expression, its biological significance, and its relationship with p53 mutations in HCC demonstrated that mRNA of cyclin D1 is associated with larger and less differentiated tumors [36,37]. The p27kip1 is strongly expressed in non-proliferating cells and has an important role in the regulation of both quiescence and progression of G1 phase by means of cyclin release. Loss of p27kip1 acts together with mutations in several oncogenes and suppressing genes, making tumor growth easier. The reduction in protein synthetized by p27kip1 has significant effects on the stage and volume of primary tumors. Therefore, p27kip1 has been described as a crucial negative regulator of HCC progression, and its increased expression is considered an independent variable in favorable prognosis in HCC [38,39]. Reduced expression of p21WAF1 is mainly related with the mutation of gene p53 in HCC, also contributing to hepatocarcinogenesis. However, loss of p21WAF1 was not identified as an independent factor for poor prognosis in HCC [38]. In terms of frequency, the most common molecular changes in HCC are: p53 (20–70%), cyclin D (11%), p16ink4 (0–50%), Rb (15%), and β-catenin (16–26%). Only the increased expression of p53 was reported in association with gene interaction in hepatitis B virus and exposure to aflatoxin [40]. However, the involvement of this toxin with p53 changes in the genesis of HCC in Brazil, as observed in the present study, had not been described until now. Although the p53 pathway has an important role in HCC pathogenesis when cirrhosis is present,
changes in the cell cycle regulator genes p21WAF1/CIP1 and p27KIP1 are more common in HCC cases that do not involve cirrhosis [41]. These changes may be, at least in part, attributed to aflatoxin exposure, hence confirming the molecular changes in genes p21WAF1/CIP1 and p27KIP1, as identified in the present study.

PB has been detected in the nucleus, where it is associated with retinoblastoma (Rb) and p53 proteins. PB induces changes in transcription factors, resulting in the inhibition of the cell cycle and apoptosis induction [42]. PB tumor suppressing action was associated with nuclear expression in neoplastic cells of several tumors [17,43]. In addition, during normal tumor suppressing function, PB reduces the nuclear translocation of NFkB mediated by TNF-α [44]. On the other hand, PB is involved in the stabilization of mitochondrial proteins and reduction of oxidative stress in the chronic phase of several diseases [44]. As for HCC, PB is followed by anti-neoplastic effects such as blockage of proliferation and induction of apoptosis [42], and increased PB levels were observed in HCC cells in humans [45]. Thus, changes in PB expression related to p53 was observed in human HCC samples from patients exposed to aflatoxin, with PB overexpression even in non-neoplastic livers, corroborating aflatoxin participation in oxidative stress pathways.

In our study, HCC AFb1+ cases had increased expression of p53, cyclin D1, p21, and β-catenin in relation to HCC AFb1+ livers. This pattern was also maintained in CV and AC cases, and was more important in the latter group. The opposite was observed in relation to p27, p16, and Rb expression. These data are in accordance with a previous study that showed that the Rb and p53 pathways are somewhat affected by the development of HCC of different etiologies, because of common mechanisms during the progression from chronic hepatitis lesions to cirrhosis. However, HCC cases that were more related to alcoholism showed greater frequency of changes in the Rb and p53 pathways than HCC linked to viral hepatitis. Suppression of Rb expression was inversely proportional to the suppression of p16 expression. The suppression of one or the other, though, culminates with the activation of the cyclin pathway, stimulating cell proliferation [46]. Additionally, a close relationship was observed between aflatoxin-induced depletion of gene Rb, development of HCC, and suppression of the Rb pathway promoting the activation of the cyclin pathway and tumor progression [47]. It was also reported that exposure to aflatoxin potentiates carcinogenesis associated with hepatitis B, provoking mutations and increased expression in gene p53 thus leading to synthesis of p53 anomalous proteins that do not perform their tumor-suppressing role adequately [48]. Increased expression of β-catenin was also reported in HCC [49].

In the present experiment, frozen samples of liver were not available in quantities as much as paraffin-embedded liver samples, which are commonly collected from autopsies and biopsies. Given that AFb1 residues could only be determined in frozen samples, our sampling number resulted greatly restricted especially within the liver diseases containing residual AFb1. Therefore, further studies are necessary to provide dose-response relationships between AFb1 residues in human liver samples and the abnormalities described in cell cycle or tumor suppressor pathway for the development of HCC.

5. Conclusion

Results of this study demonstrated that autopsied patients with liver disorders in São Paulo, Brazil, were exposed to dietary aflatoxins, and that residual AFb1 in liver negatively affected the p53 and protein Rb pathways in HCC. Moreover, the presence of AFb1 in cirrhotic livers warrants concern about the potential contribution of dietary aflatoxin for the disease progression during VC and AC.
