ABSTRACT

We performed millimeter observations in CO lines toward the supernova remnant (SNR) G127.1+0.5. We found a molecular filament at 4–13 km s⁻¹ consisting of two distinct parts: a straight part coming out of the remnant region and a curved part in the remnant region. The curved part is coincides well with the bright SNR shell detected in 1420 MHz radio continuum and mid-infrared observations in the northeastern region. In addition, redshifted line wing broadening is found only in the curved part of the molecular filament, which indicates a physical interaction. These provide strong evidences, for the first time, to confirm the association between an SNR and a pre-existing long molecular filament. Multi-band observations in the northeastern remnant shell could be explained by the interaction between the remnant shock and the dense molecular filament. RADEx radiative transfer modeling of the quiet and shocked components yield physical conditions consistent with the passage of a non-dissociative J-type shock. We argue that the curved part of the filament is fully engulfed by the remnant’s forward shock. A spatial correlation between aggregated young stellar objects (YSOs) and the adjacent molecular filament close to the SNR is also found, which could be related to the progenitor’s activity.

Key words: ISM: individual objects (G127.1+0.5) – ISM: molecules – ISM: supernova remnants

1. INTRODUCTION

Core-collapse supernovae are thought to be commonly located in the vicinity of molecular clouds (MCs), due to their short lifetime after being born in giant MCs. Therefore, the subsequent supernova remnants (SNRs) may encounter these MCs in their evolution. In practice, it is difficult to confirm such interactions because of the presence of extreme spectral and spatial complexities in studying the widespread molecular gases in the galactic plane where most SNRs are found. To date, there are only 34 SNRs (∼12% of known SNRs in our Galaxy, in contrast to about half of them indicated by Reynoso & Mangum 2001) confirmed to be interacting with MCs, and most of them were found through the detection of 1720 MHz OH masers (catalogued by Jiang et al. 2010, see references therein). The shock-excited 1720 MHz OH maser is a signpost for SNR–MC interaction, but it is only available in particular physical conditions, i.e., in a moderate non-dissociative C-type shock (Wardle & Yusef-Zadeh 2002). Since MCs are in different evolutionary stages, with different physical conditions at different positions within it, there should be various kinds of interactions between SNRs and MCs. It is important to study different kinds of interactions to figure out the role of SNRs in their parent MCs’ evolutions, e.g., triggering the next generation of star formations.

SNR G127.1+0.5 has been identified as a shell-type SNR by Caswell (1977) and Pauls (1977). Together with the central compact sources, they have been studied in many wavelengths: radio (Salter et al. 1978; Pauls et al. 1982; Fuerst et al. 1984; Joncas et al. 1989; Leahy & Tian 2006; Sun et al. 2007), optical (Xilouris et al. 1993), and X-ray (Kaplan et al. 2004). Its radio feature, which is has been studied very well, shows a fairly circular shell peaked in north–northeast with the polarization B-vectors following the shell (Sun et al. 2007), and a spectral index of 0.43 ± 0.1 (Leahy & Tian 2006). Diffuse optical emission in the SNR has been detected (Xilouris et al. 1993), but no diffuse X-ray emission was found either by Chandra observation toward the central region (Kaplan et al. 2004) or by the ROSAT all-sky survey (Leahy & Tian 2006). No instantly associated neutron star has been detected in the SNR (Kaplan et al. 2004). The distance to the SNR is not clear either; the distance is mostly based on the SNR’s assumed association with the open cluster NGC 559, which coincides in position with the SNR in previous works, hence the basic evolutionary facts of the SNR are still uncertain. Nevertheless, previous studies have revealed the possibility of an SNR–MC interaction. If such an association is established, we could better understand not only this particular SNR but also a different kind of SNR–MC interaction, i.e., without the detection of a 1720 MHz OH maser. In this work, we present our CO line observations toward the SNR G127.1+0.5. We describe the observations and results in Sections 2 and 3, respectively. In Section 4, we discuss the interpretation and derive the characteristic parameters of the SNR–MC interaction and SNR evolution. The conclusions are summarized in Section 5.

2. OBSERVATIONS

The observations of millimeter molecular emissions toward SNR G127.1+0.5 is part of the Milky Way Scroll Painting—CO line survey project¹ operated by Purple Mountain Observatory (PMO), which were made from 2011 November to 2012 February with the 13.7 m millimeter-wavelength telescope of the Qinghai station of PMO at Delingha.² A superconductor–insulator–superconductor (SIS) superconducting receiver with a nine-beam array was used as the front end (Shan et al. 2012). Three CO lines were simultaneously observed, J=1–0 at the upper sideband (USB) and two other lines at the lower sideband (LSB). Other observations are available at http://mirror.radiocast.csdb.cn/zhuangtaibaogao.php

¹ http://mirror.radiocast.nsdic.cn/yhhjindex.php
² Status Report on the 13.7 m Millimeter-Wave Telescope for the 2011–2012 Observing Season is available at http://mirror.radiocast.csdb.cn/zhuangtaibaogao.php
other lines, $^{13}$CO ($J=1$–$0$) and $^{18}$O ($J=1$–$0$), at the lower sideband (LSB). Typical system temperatures were around 210 K for USB and around 130 K for LSB, and the variations among different beams are less than 15%. The total of pointing and tracking errors is about 5′. The half-power beam width (HPBW) is 52″. The main-beam efficiencies during the observing epoch were $\sim$44% for USB with the differences among the beams less than 16%, and $\sim$48% for LSB with the differences less than 6%. We mapped a 100′ × 100′ area that contains the full extent of SNR G127.1+0.5 via on-the-fly (OTF) observing mode, and the data is meshed with the grid spacing of 30″. A Fast Fourier Transform (FFT) spectrometer with a total bandwidth of 1000 MHz and 16,384 channels was used as the back end. The corresponding spectral resolutions were 0.17 km s$^{-1}$ for $^{12}$CO ($J=1$–$0$) and 0.16 km s$^{-1}$ for both $^{13}$CO ($J=1$–$0$) and C$^{18}$O ($J=1$–$0$). The baseline subtraction was performed with a linear fit. The average rms noises of all final spectra are about 0.5 K for $^{13}$CO ($J=1$–$0$) and about 0.3 K for $^{13}$CO ($J=1$–$0$) and C$^{18}$O ($J=1$–$0$). All data were reduced using the GILDAS/CLASS package.

The 1420 MHz radio continuum emission data were obtained from the Canadian Galactic Plane Survey (CGPS; Taylor et al. 2003). The infrared (IR) photometric data were extracted from the Two-Micron All Sky Survey (2MASS; Skrutskie et al. 2006) and the survey of the Wide-field Infrared Survey Explorer (WISE; Wright et al. 2010). The 2MASS survey provides data in the near-IR $JHK_s$ bands with a 10σ point-source detection level better than 15.8, 15.1, and 14.3 mag, respectively. WISE achieved 5σ point source sensitivities better than 0.08, 0.11, 1, and 6 mJy at 3.4, 4.6, 12, and 22 μm, respectively. The angular resolutions are $6′1, 6′4, 6′5,$ and $12′0$ in the four WISE bands, respectively. We used 2MASS $HK_s$ bands and the first three WISE bands for point source analysis, and selected the point source with photometric error less than 0.1 mag for 2MASS data and signal-to-noise ratio greater than 5 for WISE data.

3. RESULTS

Figure 1 shows the $^{12}$CO and $^{13}$CO intensity maps over the velocity range of 4–13 km s$^{-1}$ with an interval of 1 km s$^{-1}$. No significant C$^{18}$O emission was detected over any region. There is a short $^{12}$CO filament in the northeastern region, with some corresponding $^{13}$CO emissions. Some diffuse $^{12}$CO emissions are also visible in the northwestern region, but there is no corresponding significant $^{13}$CO emission detected. The prominent feature is a long filament that extends from the bottom-left corner to the central region. In comparison with the 1420 MHz continuum emission, we can divide the filament into two parts: a part coming out of the remnant region and a part in the remnant region. The filament coming out of the remnant region is only present at velocities less than $\sim10$ km s$^{-1}$, and it is straight over all the velocities. The filament in the remnant region is visible over all the velocities, and it is only straight at velocities less than $\sim6$ km s$^{-1}$. At higher velocities, the filament is curved and coincident with the bright radio shell of the remnant. At the velocities over $\sim10$ km s$^{-1}$, we could only see the most curved part of the filament, which is at the position of the radio peak. The $^{13}$CO emission of the long filament is mainly present at low velocities. There is no prominent $^{13}$CO emission in the curved part. In the integrated intensity map of $^{12}$CO in the velocity range of 6–7 km s$^{-1}$, we could clearly see the long filament with the straight part coming out of the remnant region and the curved part in the remnant region, indicated by the blue and red arrows, respectively (Figure 2). We found a compact broad redshifted CO wing that is only present in the curved part of the filament around $(l,b) = (127.4, 0.7)$, where the radio continuum shows a shell peak (see Figure 2). This redshifted component is clearly visible in the $^{12}$CO ($J=1$–$0$) spectrum from the curved part of the filament (Figure 3). These are strong evidences of the interaction between the SNR and the filament. Because of the compression and amplification of the magnetic field in such interaction, the radio peak can also be explained. Such extensive CO wings have also been found in other SNRs, for example, SNR W28 (Arikawa et al. 1999; Reach et al. 2005) and SNR IC 443 (Dickman et al. 1992; Wang & Scoville 1992; Seta et al. 1998; Snell et al. 2005). However, in W28 and IC 443, the CO wings are very intense, and the velocity span could be over $\sim50$ km s$^{-1}$. It may indicate different amounts of shocked molecular gas (see Section 4.1 for further discussion).

5 http://www.iram.fr/IRAMFR/GILDAS
The position–velocity map along the whole filament shows some velocity distortions, with a velocity shift of \( \sim 1 \, \text{km s}^{-1} \). Similar velocity distortions have been found in other filamentary molecular clouds (e.g., Bally et al. 1987; Kirk et al. 2013; Zhang et al. 2014), which are probably common and may indicate a helical magnetic field in the filament (Falgarone et al. 2001). However, the situation is more complicated in the curved part of the filament, which contains both a broad redshifted wing around the most curved part and highly blueshifted bumps (\( \sim 2 \, \text{km s}^{-1} \)) around the conjunction point between the straight part and the curved part. It suggests that such a velocity distortion could be enhanced by the impact of an SNR shock; in particular, the velocity shift will be enlarged by a shock propagating along the filament.

We did not find any morphological correlations for the other velocity components other than the \( \sim 5 \, \text{km s}^{-1} \) one in our observations. In the velocity range of \(-10–20 \, \text{km s}^{-1}\), there are two components, one is at \( \sim 2 \, \text{km s}^{-1} \) and the other is at \( \sim 5 \, \text{km s}^{-1} \) (see the left panel of Figure 3). Both of these components are probably located in the local arm, but are from different subscale structures. Note that the local standard of rest (LSR) velocity of the Perseus arm is around \(-50 \, \text{km s}^{-1}\) in this direction (Dame et al. 2001), and the distance is about 2 kpc (Xu et al. 2006; Hachisuka et al. 2006). However, for a source at the LSR velocity of \(-50 \, \text{km s}^{-1}\), the kinematic distance is about 5 kpc by applying the rotation curve of Brand & Blitz (1993) together with the galactocentric distance of 8.0 kpc (Reid 1993) and the circular rotation speed of 220 km s\(^{-1}\). The reason for such discrepancy is the anomalous motion in this portion of the Perseus arm, which could be as large as 22 km s\(^{-1}\) (Xu et al. 2006). Considering this peculiar motion, the velocity difference is still too large to place the velocity component at \( \sim 5 \, \text{km s}^{-1} \) in the Perseus arm. The LSR velocity in the local arm is around 0 km s\(^{-1}\), and the maximum systematic velocity is \( \sim 2 \, \text{km s}^{-1} \) (Brand & Blitz 1993), which is smaller than 5 km s\(^{-1}\).

If we consider the contribution of an expanding shell near our solar system, which is known as the Gould Belt/Lindblad Ring, the \( \sim 5 \, \text{km s}^{-1} \) systematic velocity could be understood; accordingly, the distance to this component would be about 300 pc (Bally 2008, and references therein). Alternatively, for

Figure 2. Left: integrated intensity map of \(^{12}\text{CO (J} = 1–0)\) emission in the velocity range of 6–7 km s\(^{-1}\), overlaid with the same 1420 MHz radio continuum contours as in Figure 1. The blue and red arrows indicate the straight and curved parts of the filament, which are out of the remnant and in the remnant, respectively. Right: position–velocity map of \(^{12}\text{CO (J} = 1–0)\) emission integrated over the strip region indicated by the arrows in the left panel, superposed with the intensity contours from \(1 \sigma\) (0.53 K) to \(5 \sigma\) in steps of \(1 \sigma\). The blue and red arrows correspond to that in the left panel. (A color version of this figure is available in the online journal.)

Figure 3. Average \(^{12}\text{CO (J} = 1–0)\) and \(^{13}\text{CO (J} = 1–0)\) spectra over the straight (left) and curved (right) parts of the filament, which are indicated by the blue and red arrows, respectively, in Figure 2. The \(^{13}\text{CO (J} = 1–0)\) spectra have been multiplied by 5 for better visibility. The spectra are fitted by two Gaussian components, except for the \(^{12}\text{CO (J} = 1–0)\) spectrum of the curved part, which is fitted by three Gaussian components. The fitting results are shown by the black dashed lines (see the fitted parameters in Table 1).

(A color version of this figure is available in the online journal.)
such a small velocity difference, it could also be accounted for by random cloud motion. In this case, we could use half the distance to the Perseus arm, about 1 kpc, as a maximum. 

\[ 13\text{CO} \ (J = 1\text{–}0) \] emissions are prominent for these two velocity components, with their line centers consistent with that of \[ 12\text{CO} \ (J = 1\text{–}0) \] emission, while the \[ 12\text{CO} \] emission from the curved part of the filament is broadened in the red wing (see the right panel of Figure 3), and there is no corresponding \[ 13\text{CO} \] emission detected for the broadened red wing. In fact, the peak of the \[ 12\text{CO} \] emission is also shifted a little relative to the peak of the \[ 13\text{CO} \] emission in addition to the red-wing broadening. Considering that the absence of corresponding \[ 13\text{CO} \] emission contributes most of the uncertainty in our spectral analysis, we used only one component to fit the \[ 12\text{CO} \] redshifted component. The upper limit of the peak \( T_{\text{mb}} \) for the \[ 13\text{CO} \] emission of the redshifted component is 0.03 K and the upper limit of full width at half maximum (FWHM) is 6.0 km s\(^{-1}\), which are the rms of the spectrum and the FWHM of the corresponding \[ 12\text{CO} \] component, respectively. Except for the \[ 12\text{CO} \ (J = 1\text{–}0) \] spectrum from the curved part of the filament fitted by the three Gaussian components, we used two Gaussian components to fit all other spectra (see the fitting results in Figure 3). The fitted and derived parameters are listed in Table 1. 

We used two methods to estimate the \( H_2 \) column density and the molecular mass. In the first method, we assumed local thermodynamical equilibrium (LTE) for the gas and optically thick conditions for the \[ 13\text{CO} \ (J = 1\text{–}0) \] line and used the \[ 13\text{CO} \] abundance of \( 1.4 \times 10^{-6} \) (Ripple et al. 2013). For comparison, we also estimated the \( H_2 \) column density by applying the conversion factor \( N(H_2)/W(12\text{CO}) \approx 1.8 \times 10^{20} \text{ cm}^{-2} \text{ K}^{-1} \text{ km s}^{-1} \) (Dame et al. 2001). The differences between the \( H_2 \) column densities derived by the two methods are partly caused by the small filling factors of the \[ 13\text{CO} \] emission, since there are less \[ 13\text{CO} \] emissions than \[ 12\text{CO} \] emissions in the filament. The effect is not significant, however, because the \( H_2 \) column density will not change much in the case of a small filling factor. Applying the possible filling factor of \[ 13\text{CO} \] emission of 0.15, which is the ratio of the number of points with bright \[ 12\text{CO} \] emission and the number of points with bright \[ 13\text{CO} \] emission, the \( H_2 \) column density of the straight part of the filament becomes \( 3.7 \times 10^{20} \text{ cm}^{-2} \). The derived molecular gas masses for the filament are all about two orders lower than the virial masses, indicating that the filamentary molecular cloud is not confined by gravity (maybe by magnetic field; Contreras et al. 2013).

### 4. DISCUSSION

#### 4.1. Physical Conditions of the Molecular Gas

According to the fitted parameters of the molecular filament (see Table 1), we ran the RADEX radiative transfer code (van der Tak et al. 2007) with the LAMDA molecular data files (Schöier et al. 2005) to simultaneously model the \[ 12\text{CO}(J = 1\text{–}0) \] and \[ 13\text{CO}(J = 1\text{–}0) \] line emissions. The two molecular lines are sensitive to different physical parameters, hence the joint modeling could help constrain the physical state of the molecular gas. In the modeling, we chose the slab option in RADEX to mimic the geometries of the shocked and filament-shaped molecular clouds, and assumed a \[ 13\text{CO} \] abundance of \( 6 \times 10^{-6} \) (Ripple et al. 2013) and an isotopic abundance of \[ 12\text{CO}/13\text{CO} \approx 70 \] (Millam et al. 2005). In running RADEX, we set the collisional partner to be \( H_2 \) and set the temperature of the background radiation to be the cosmic microwave background (CMB) temperature, that is, 2.73 K. We explored the physical parameter space over excitation temperature and density to find the best-fit model and then calculated 90% confidence intervals on the best-fit parameters by applying the \( \chi^2 \)-squared statistics. We estimated the best-fit results using different plausible column densities; however, we could only get the lower limits for

---

**Notes.**

\( ^a \) No \( 13\text{CO} \) emission visible, the error is the rms of the spectrum.

\( ^b \) Assuming local thermal equilibrium (LTE) and optical thickness to \( 12\text{CO} \) emission. Filling factor is assumed to be 1, since the width of the filament is much larger than the beam size.

\( ^c \) Derived from \( 13\text{CO} \) column density by using the \( 13\text{CO} \) abundance of \( 1.4 \times 10^{-6} \) (Ripple et al. 2013). For comparison, we also show the values in the brackets, which are estimated by using the conversion factor \( N(H_2)/W(12\text{CO}) \approx 1.8 \times 10^{20} \text{ cm}^{-2} \text{ K}^{-1} \text{ km s}^{-1} \) (Dame et al. 2001).

\( ^d \) Calculated using \( C \times k_2 \times L \times \Delta v^2 \), where \( k_2 = 105 \) (MacLaren et al. 1988), \( C = 0.65 \) is the correction factor for the filament-shaped cloud, \( L \) is the length of the filament, and \( \Delta v \) is the velocity width (FWHM).

\( ^e \) \( d_3 = d/(1 \text{ kpc}) \), where \( d \) is the distance to SNR G127.1+0.5 (see Section 4.2).

\( ^f \) The assumption of optical thickness for \( 12\text{CO} \) emission is not valid here.
some of them. Figure 4 shows the best-fit parameters and their confidence intervals.

We could distinguish two kinds of molecular gases in Figure 4: one is cold and dense from the straight molecular filament and the rest component toward the curved molecular filament, which is consistent with quiet molecular clouds; the other is hot and about two orders of magnitude denser from the redshifted component toward the curved filament, which is consistent with a shocked molecular cloud.

The fitting results of quiet molecular gases for the column densities lower than $10^{21}$ cm$^{-2}$ only give lower limits of number densities. Then, the lengths in the line of sight (LOS) could be derived as $N(H_2)/n < 0.2$ pc, which is too small compared to the width of the filament ($\sim 2$ d$_{1}$ pc), while the best-fit models are found for the column densities of $10^{21}$ cm$^{-2}$, which give densities of about 300 cm$^{-3}$ and temperatures of about 5 K.

Further, the corresponding lengths in the LOS are $\sim 1$ pc, which is consistent with the width of the straight filament. These column densities are consistent with those derived from the assumptions of LTE and optically thick $^{12}$CO ($J = 1 - 0$) and from the using the conversion factor (see Table 1).

The best-fit result for the redshifted component gives a density of $\sim 6 \times 10^{4}$ cm$^{-3}$ and a temperature of $\sim 1000$ K with the column density of $3 \times 10^{20}$ cm$^{-2}$. Note that, for the redshifted component, the optical depth of the $^{13}$CO ($J = 1 - 0$) line emission is not large because of the large velocity gradient (broadened line) and non-detection of corresponding $^{13}$CO ($J = 1 - 0$) line emission, so the temperature could not be constrained well here. Besides, the molecular data are not enough to handle temperatures higher than 500 K in running RADEX. In our fitting result, the temperature ranges from a hundred to over a thousand Kelvin. Considering the non-detection of OH (1720 MHz) line emission (Frail et al. 1996), the temperature is probably higher than 125 K (Wardle & Yusef-Zadeh 2002). However, the missing OH (1720 MHz) line emission may also indicate a low column density like that in a J-type shock. In the case of weakly magnetized shock, i.e., a J-type shock, we can derive the post-shock temperature as $
abla T/T_{0} = 3/16$ for a large Mach number, $\mu = 2.33$ is the average atomic weight (Lesaffre et al. 2013), $m_{A}$ is the mass of the hydrogen atom, $v_{\text{cloud}}$ is the velocity of the shock in the filament, and $k_B$ is Boltzmann constant. The molecular shock velocity is $v_{\text{cloud}} = 4v_{\text{shift}}/3 \approx 5$ km s$^{-1}$, where $v_{\text{shift}}$ is the velocity of post-shock molecular gas. Hence, the calculated post-shock temperature is $\sim 1300$ K, which is consistent with the best-fit result. If the shock is highly magnetized, i.e., a C-type shock, the post-shock temperature would be much smaller than that in a J-type shock because the heating is spread out over a much larger region, especially for a slow shock (Lesaffre et al. 2013). Therefore, the molecular gas is probably heated and compressed by a non-dissociative J-type shock, but the existence of a C-type shock cannot be excluded.

Adopting the best-fit column density and the number density of the redshifted component, we have the length in the LOS of $l \sim 1.6 \times 10^{-3}$ pc, which is about three orders of magnitudes less than the width of the straight filament. Since the thickness of shocked molecular gas (represented by $s$) is less than the length in the LOS ($s \lesssim l$), which is very small, the shocked molecular gas is probably in a very thin sheet. We consider that all shocked molecular gas is compressed into this thin sheet, which is reasonable for the slow shock. Therefore, the thickness of the corresponding unshocked gas is $s_0 = s \times n_{\text{shock}}/n_{\text{cloud}} \lesssim l \times n_{\text{shock}}/n_{\text{cloud}} \sim 0.32$ pc, where $n_{\text{shock}}$ is the density of shocked molecular gas, and $n_{\text{cloud}}$ is the density of quiet molecular gas, which is approximately one-sixth of the width of the straight filament. The time for the shock to pass through such a distance is $t_{\text{cloud}} = s_0/v_{\text{cloud}} \lesssim 6 \times 10^3$ yr. Applying the column density of $3 \times 10^{20}$ cm$^{-2}$, we obtain the mass of the shocked molecular gas to be $100d^2_{1} M_{\odot}$ and the kinetic energy of $\sim 1.6 \times 10^{46} d_{1}^2$ erg which provides a lower limit for the SNR energy.

The amount of shocked molecular gas is remarkably less than that in W28 and IC 443. In W28, there are $\sim 2 \times 10^5 M_{\odot}$ shocked molecular gases, with the total kinetic energy of $\sim 5 \times 10^{48}$ erg (Arikawa et al. 1999). In IC 443, there are $500-2000 M_{\odot}$ shocked molecular gases, with a possible total kinetic energy of $\sim 3-13 \times 10^{48}$ erg (Dickman et al. 1992). Both W28 and IC 443 are interacting with large MCs ($\sim 4 \times 10^5 M_{\odot}$ for W28, Arikawa et al. 1999; $\sim 1 \times 10^4 M_{\odot}$ for IC 443, Cornell et al. 1977), and their shock fronts are blocked by the surrounding MCs. The case is different in G127.1+0.5, which is interacting with a small filamentary MC that could be engulfed in the remnant. The overall densities and temperatures of quiet molecular gases associated with W28 ($\sim 10^3$ cm$^{-3}$ and $\sim 20$ K, respectively; Arikawa et al. 1999) and G127.1+0.5 are similar. However, the detailed structures of the associated MCs may be very different. The properties of their shocked molecular gases are found to be different, taking into account that W28 is associated with 1720 MHz OH masers (Clausen et al. 1997), and G127.1+0.5 is not. The origin of this difference is not clear. It needs more observations for further investigation.

4.2. Nature of SNR G127.1+0.5

Both morphological correspondence and dynamical evidence indicate an association between SNR G127.1+0.5 and the molecular filament. We also examined the H I 21 cm line emission data from CGPS, and found no absorption feature toward the remnant, which is consistent with the location of the molecular filament at the far side of the remnant (red-wing broadening). This association facilitates us to determine the kinematic distance to the remnant. As shown above, the molecular filament is in the local arm, so is the remnant. If the
molecular filament is in the Gould Belt/Lindblad Ring, the distance of the SNR is $d \sim 300$ pc, and the radius is $r_s \sim 2.3$ pc. Moreover, the detection of optical emission probably enhances our results of shock–cloud interaction and the close distance; however, the overlapping of the open cluster NGC 559 and the nearby northeastern H II region prohibit a detailed morphological study (Xilouris et al. 1993). The distance to the open cluster NGC 559 is $d \sim 1.3$ kpc (Rose & Hintz 2007), and there is an H I bubble at $-14$ km s$^{-1}$ surrounding it, of which the kinematic distance is consistent with that of NGC 559 (Leahy & Tian 2006). Based on our observations, there is also a CO cloud at $-13$ km s$^{-1}$, but with a smaller extension than H I cloud, which is probably the molecular counterpart of H I gas. The bubble structure shown in H I emission cannot be distinguished in our CO observations, which might be due to the limited sensitivity. The distance to the NGC 559 and H I bubble system is about half the distance to the Perseus arm. It shows that the local arm in this direction could be quite extended. We cannot exclude the association of the SNR with NGC 559 as well as with the H I bubble, although we have not found any H I absorption feature toward the remnant. If they are associated, the distance of the SNR is $d \sim 1.3$ kpc, and the radius is $r_s \sim 10$ pc.

There are radio emissions beyond the filament in the northeastern region, which may be caused by a projection effect. In an extreme case, if the filament is located at the boundary of the remnant, the velocities between the forward shock and the molecular shock should be similar, since the two shocks have passed through about the same distance in the same time ($t_{\text{cloud}} \lesssim 6 \times 10^4$ yr as shown above). Consequently, the density contrast is $\chi = n_{\text{cloud}}/n_0 \sim \beta v_s^2/v_{\text{cloud}}^2 \sim 1$, where $n_0$ is the density of the circumstellar or interstellar medium (CSM/ISM), $v_s$ is the forward shock velocity, and the constant $\beta$ is adopted as unity (McKee & Cowie 1975; Orlando et al. 2005). If the density of the CSM/ISM is actually as large as $n_{\text{cloud}} \sim (300$ cm$^{-3}$), the accumulated gas swept up by the remnant shock will form a massive shell of about $2.8 \times 10^4 M_\odot$, which is much larger than the mass of the filament. We have not found such a shell in our observations. On the other hand, if the radial direction is approximately perpendicular to the LOS, the forward shock should have been surrounding the filament after the encounter, and the forward shock will propagate about 10$d_1$ times farther away than the molecular shock after the encounter. Therefore, its velocity is also about 10$d_1$ times larger than the molecular shock, which is $\sim 50d_1$ km s$^{-1}$. In this case, the density contrast is $\chi \sim 50d_1^2$, and the density of the CSM/ISM is $n_0 = n_{\text{cloud}}/\chi \sim 6d_1^{-1}$ cm$^{-3}$, which is more reasonable. Therefore, the velocity of the forward shock is probably $v_s \sim 50d_1$ km s$^{-1}$, and the corresponding post-shock temperature is $\sim 10^5$ K. The age of the remnant is greater than $t_{\text{cloud}}$, which is $\lesssim 8 \times 10^4$ yr. It is not well constrained yet, but this still indicates that the remnant is relatively old compared to a young SNR, e.g., SNR W49B (Zhou et al. 2011).

The low post-shock temperature indicates that the remnant is in the radiative phase, which is also confirmed by the non-detection of X-ray emission in ROSAT All-Sky survey data. The age of the remnant in the radiative phase can be estimated as $t = 2r_s/(7v_s) \sim 4.3 \times 10^4$ yr (McKee & Ostriker 1977), and the result is consistent with that shown above. Based on the numerical solutions and analytical fitting for an SNR in the pressure-driven snowplough phase by Cioffi et al. (1988), the explosion energy could be obtained as:

$$E = 6.8 \times 10^{43} \frac{v_s}{1 \text{ km s}^{-1}}^{1.16} \frac{r_s}{1 \text{ pc}}^{3.16} \rho_m^{0.16} \text{ erg}$$

$$\sim 6.8 \times 10^{49} d_1^{3.35} \text{ erg}, \quad (1)$$

where $\rho_m = Z/Z_\odot$ is the metallicity parameter, which is set to 1. The explosion energy, $1.6 \times 10^{50}$ erg, derived by applying the distance of 1.3 kpc, is lower than the nominal value ($10^{51}$ erg), and it is $1.2 \times 10^{48}$ erg if the distance is 300 pc, which is probably too small. It may support the large distance of the remnant. Evidences of such sub-energetic supernova explosion have been found in other SNRs, e.g., SNR DA530 (Jiang et al. 2007), SNR 3C 58 (Rudie & Fesen 2007), and SNR G310.6-1.6 (Renaud et al. 2010), which could originate from the core-collapse supernova explosion of relatively low-mass ($\sim 8$–10 $M_\odot$) stars (Nomoto 1987).

4.3. Possible Associated Star Formation

There is corresponding mid-IR emission from the curved filament, but no mid-IR emission is seen from the straight filament (see Figure 5). These mid-IR emissions probably originate from the hot dust that is heated by the remnant shock. There is also mid-IR emission in the northeastern region outside the remnant, which may originate from the hot dust related to the nearby H II region G127.5+1.1 (Fich & Terebey 1996).

Using the IR data we selected the young stellar objects (YSOs) to investigate their spatial distribution. In our examination, we only focus on the disk-bearing young stars, since their IR colors are distinctly different from those of diskless objects. We cannot distinguish diskless young stars from unrelated field objects based on IR colors alone. Following the criteria described in Koenig et al. (2012), we selected candidate disk-bearing young stars, where the contaminations from
Figure 6. Schematic view of SNR G127.1+0.5 based on our $^{12}$CO ($J=1-0$) and $^{13}$CO ($J=1-0$) observations. The red star denotes the position of the progenitor’s stellar wind. The dotted line denotes the possible border of the progenitor’s stellar wind.

(A color version of this figure is available in the online journal.)

eXtragalactic sources (star-forming galaxy and active galactic nucleus), shock emission blobs, and polycyclic aromatic hydrocarbon (PAH) emission objects were removed based on their locations in the $[3.4]-[4.6]$ versus $[4.6]-[12]$ color–color diagram and their WISE photometry. For the sources that are not detected in the WISE [12] band, we constructed the $K_s-[3.4]$ versus $[3.4]-[4.6]$ color–color diagram based on their dereddened photometry in the WISE [3.4] and [4.6] bands, in combination with the dereddened 2MASS $K_s$ photometry. To deredden the photometry, we estimated the extinction by their locations in the $J-H$ versus $H-K_s$ color–color diagram as described in Fang et al. (2013).

We found that the majority of aggregated YSOs are coincident with the MCs at $\sim-50$ km s$^{-1}$ that are located in the Perseus spiral arm at a distance of $\sim2$ kpc (Xu et al. 2006), except that a cluster of YSOs at ($l \sim 127.5$, $b \sim 0.93$) shows no morphological correlation with the velocity component at $\sim-50$ km s$^{-1}$, and no association to the mid-IR emission either. Instead, this cluster of YSOs is located at the top end of the northeastern molecular filament at $\sim5$ km s$^{-1}$ (see Figure 1). There is no morphological correlation found between the cluster of YSOs and other velocity components. It suggests a star-forming activity at the top end of the northeastern molecular filament close to the SNR. Since the shock of the remnant does not reach yet here, the star-forming activity cannot be related to the remnant shock. Nevertheless, the stellar wind of the progenitor of the remnant could trigger star formation here (see Figure 6). The lack of mid-IR emission as well as $^{13}$CO emission around the YSOs may indicate that the diffuse tenuous gas was evacuated by the stellar wind that triggered the collapse of the dense gas in the meantime.

5. CONCLUSIONS

We have performed millimeter observations in CO lines toward SNR G127.1+0.5. We found a molecular filament at $4-13$ km s$^{-1}$ that consists of two distinct parts: a straight part coming out of the remnant region and a curved part in the remnant region. The deviation from virial equilibrium suggests that the filament is not confined by gravity (maybe by magnetic field). The curved part is well consistent with the bright SNR shell detected in the 1420 MHz radio continuum and mid-IR observations. Further, redshifted line wing broadening is also found only in this curved part of the molecular filament, which indicates a physical interaction. These provide strong evidences, for the first time, to confirm the association between an SNR and a pre-existing long molecular filament. Multiband observations in the northeastern remnant shell could be explained by the interactions between the remnant shock and the dense molecular filament. With the association between the SNR G127.1+0.5 and the molecular filament at $\sim5$ km s$^{-1}$, we could place the SNR in the Gould Belt/Lindblad Ring and at a kinematic distance of about 300 pc. Alternatively, there is also another possibility that the molecular filament has a peculiar motion, and the remnant may be associated with the open cluster NGC 559 and located at a farther distance of about 1.3 kpc. It is supported by the estimation of explosion energy.

Radiative transfer modeling of the physical conditions of the molecular gas in the filament in combination with the assumed columnar-shaped filament yields a column density of $\sim10^{21}$ cm$^{-2}$, a density of $\sim300$ cm$^{-3}$, and a temperature of $\sim5$ K for the quiet component. For the shocked component in the curved part of the filament, the physical parameters were found to have a column density of $\sim3 \times 10^{20}$ cm$^{-2}$, a density of $\sim6 \times 10^{3}$ cm$^{-3}$, and a temperature of $\sim1000$ K. The shocked component probably originates from the passage of a non-dissociative J-type shock. The interaction details could be well explained if the curved part of the filament is fully engulfed by the remnant forward shock, and it indicates a dense CSM/ISM environment surrounding the SNR ($\sim6d_1$ cm$^{-3}$) and a low explosion energy ($\sim6.8 \times 10^{53}d_1^{-1} J_{33}$ erg). It also suggests that the SNR is in radiative phase, and the age is estimated to be $\sim4.3 \times 10^4$ yr. We also found a spatial correlation between the aggregated YSOs and the adjacent molecular filament close to the SNR, which could be triggered by the progenitor’s stellar wind.

We are grateful to all members of the Milky Way Scroll Painting-CO line survey group, especially the staff of Qinghai Radio Observing Station at Delingha for the support during the observation. We thank the anonymous referee for providing very helpful comments that improved the paper and its conclusions.
