In situ microscopy of the self-assembly of branched nanocrystals in solution

Eli Sutter, Peter Sutter, Alexei V. Tkachenko, Roman Krahne, Joost de Graaf, Milena Arciniegas & Liberato Manna

Solution-phase self-assembly of nanocrystals into mesoscale structures is a promising strategy for constructing functional materials from nanoscale components. Liquid environments are key to self-assembly since they allow suspended nanocrystals to diffuse and interact freely, but they also complicate experiments. Real-time observations with single-particle resolution could have transformative impact on our understanding of nanocrystal self-assembly. Here we use real-time in situ imaging by liquid-cell electron microscopy to elucidate the nucleation and growth mechanism and properties of linear chains of octapod-shaped nanocrystals in their native solution environment. Statistical mechanics modelling based on these observations and using the measured chain-length distribution clarifies the relative importance of dipolar and entropic forces in the assembly process and gives direct access to the interparticle interaction. Our results suggest that monomer-resolved in situ imaging combined with modelling can provide unprecedented quantitative insight into the microscopic processes and interactions that govern nanocrystal self-assembly in solution.
The self-assembly of nanocrystals into ordered superstructures promises access to photonic\textsuperscript{1,2}, plasmonic\textsuperscript{3}, electronic\textsuperscript{4,5}, magnetic\textsuperscript{6} and catalytic\textsuperscript{7} functionalities that are tunable and may even be reconfigurable in real time\textsuperscript{8}. Besides technological interest, research on crystallization of colloids is driven by the recognition that they are not simply large atom equivalents but represent a form of matter with complex collective behaviour that can be controlled via the interplay of entropic, van der Waals, steric and dipolar interactions\textsuperscript{9-11}, by attaching molecular linkers such as coordinated ligands or DNA\textsuperscript{12-14}, or by using shaped particles\textsuperscript{15,14}. Understanding the structure, formation and transformation of colloidal matter requires probing particle configurations from monomers to extended periodic or aperiodic assemblies. Computer simulations provide this capability\textsuperscript{16,17}, but experiments are complicated by the need to interrogate processes in liquids that allow suspended particles to diffuse and interact freely. Larger micro-colloids can be imaged with single-particle resolution by optical microscopy\textsuperscript{18,19}, but offer limited diversity of materials and shapes\textsuperscript{20}. For nanocrystals, in situ measurements have largely been restricted to reciprocal space techniques\textsuperscript{14,21}, which yield little information on the assembly process or the underlying forces. Liquid-cell electron microscopy (LCEM) has recently been developed into a tool capable of imaging processes in liquids with nanometre resolution\textsuperscript{22-24}. LCEM has been used previously to study single-layer assembly of compact nanocrystals driven by convective transport during solvent drying\textsuperscript{25}. A large class of self-assembly processes, for instance the entropy-driven assembly of polyhedral nanocrystals\textsuperscript{15} or the DNA-guided crystallization\textsuperscript{12-14,26} and reconfiguration\textsuperscript{27} of spherical nucleic acid conjugates occurs in bulk solutions with transport by Brownian motion.

Using the example of the one-dimensional (1D) self-assembly of CdSe/CdS octapods, we demonstrate the ability of LCEM to dynamically probe such solution-phase self-assembly processes in real space with nanometre resolution. Octapods, branched nanocrystals with a complex but still highly symmetric shape\textsuperscript{28-30}, have been found to self-assemble into a variety of superstructures: interlocked 1D chains in bulk liquid, two-dimensional square lattices on substrates\textsuperscript{31} or micron-sized three-dimensional (3D) structures of aligned 1D chains\textsuperscript{31}. Strongly anisotropic interactions are thought to be key to their rich set of accessible superstructures. By real-time imaging with monomer resolution, the \textit{in situ} LCEM observations reported here establish several key aspects of the self-assembly of ordered linear chains of octapods in solution. The trimer, that is, a three-octapod chain, is the shortest stable chain of interlocked octapods. Two-octapod chains (dimers) are suppressed, which implies that they are unstable. Dynamic fluctuations and the incorporation of trimers and of longer oligomers are mostly responsible for the growth of the interlocked chains, which in this way can reach up to ~20 octapods in length. Besides tracking nucleation and growth, the need for \textit{in situ} observations is illustrated by measurements of important properties, such as the interparticle spacing in the chains. In their native solution environment, the octapod chains are much less densely packed than observed in conventional \textit{ex situ} analysis after drying or vitrification of the solvent. On the basis of the characteristics obtained from \textit{in situ} microscopy, a statistical mechanics model is built that explains the chain-length distribution (notably the absence of stable dimers), establishes the relative importance of van der Waals and entropic forces in the self-assembly, and determines the strength of the particle–particle interaction. Our findings illustrate the ability of \textit{in situ} microscopy combined with modelling to obtain detailed quantitative insight into nanocrystal self-assembly processes in solution.

**Results**

**In situ** liquid-cell electron microscopy. **In situ** microscopy was performed by scanning transmission electron microscopy (STEM) using solutions of CdSe/CdS octapods (pod length $L$~(47 ± 3) nm, $D_p$~4.2; see Fig. 1) in toluene with a nominal particle concentration of 10$^{-8}$ M, prepared according to reported methods\textsuperscript{21}.

The solution was loaded in the liquid cell and observed within a viewing area where it was held between two electron transparent Si$_3$N$_4$ membranes (see Methods). Immediately after starting the observations, there was a higher concentration of octapods near the corners of the cell (for example, Supplementary Figs 1 and 6) and along the edges of the window, whereas the centre of the cell remained less populated.

Figure 2 shows a representative sequence of liquid-cell STEM images of octapods in toluene (extracted from Supplementary Movie 1) that follows the time evolution near the boundary between high and low concentration. Initially (observation time $t$<30 s) the solution within these areas appears homogeneous, with diffuse contrast and streaking suggesting dispersed individual octapods and possibly chains submerged in the bulk solvent. As the self-assembly progresses, octapods and linear chains are clearly observed ($t$>35 s). Chains of interlocked octapods form exclusively in the region with higher concentration near the edges and corners of the viewing window (Supplementary Fig. 7). The first clear contrast is due to two short-chain segments, each containing three interlocked octapods ($t$=35 s). In the next ~20 s, additional short chains become visible and the first longer chains appear; surrounding diffuse contrast indicates continuing rapid motion in the solvent. During the further evolution, the existing chains grow longer so that the field of view becomes progressively crowded with interlocked octapod chains of different length. An overall downward directionality might be interpreted as a sign of progressive drying of the solvent and concomitant increase of the octapod density in the remaining...
solution, such as in evaporative self-assembly processes\(^{32,33}\). Further examination shows, however, that the formation of octapod chains occurs in a 3D solution environment of constant thickness, and is not significantly influenced by evaporation of the toluene solvent (see Supplementary Note 1 and Supplementary Figs 3–6,8 and 9).

Analysis of real-time image sequences allows us to develop a detailed picture of the self-assembly of 1D octapod chains in solution. Important elements, such as image contrast, predominant octapod orientations and a limited 3D imaging capability in STEM are discussed in the Methods and Supplementary Fig. 2. Figure 2 and additional data (Supplementary Movies 2–6; extracted images in Fig. 3 and Supplementary Figs 10–14) document the assembly mechanism. The process is initiated by the emergence of short segments of tightly interlocked octapod chains. The majority of chains are built from interlocked units, similar to those analysed \textit{ex situ} in vitrified solvent\(^{21}\), but observations of pairs or larger numbers of monomers interacting tip-to-tip and diffusing as a non-interlocked cluster (Supplementary Movies 2 and 3) suggest a richer set of interactions between monomers than the pod-to-pod van der Waals forces invoked so far.

Short interlocked octapod chains typically emerge from the bulk solution, which indicates that they are formed there. Observations of the fluid with focal plane near the top SiN\(_x\) membrane show the attachment and detachment of such short-chain segments as the predominant process of forming long 1D chains (Fig. 2). Chain growth is clearly a dynamic process, subject to fluctuations that add and remove segments of varying length (Fig. 3a,b). The smallest interlocked oligomer unit observed in our experiments is the trimer, that is, consists of three octapods.

A survey of a large number of chains \textit{ex situ} after opening the liquid cell (Fig. 3c) and \textit{in situ} at different stages of the assembly (Fig. 4a) shows only isolated instances of interlocked dimers, whereas trimers and longer chains are much more abundant. The addition of trimers and longer oligomers is also the predominant elementary step in chain growth (Fig. 3b), while monomer incorporation is quite rare and is often followed by detachment of the same unit, suggesting incomplete locking (for example, Fig. 3b). Two-octapod increments are occasionally seen (Fig. 3b) but the absence of stable dimers in the solution suggests that these instances may actually represent a sequential addition of monomers or of non-interlocked dimers.

The observed solution-phase self-assembly deviates from a classic nucleation and growth scenario, which presumes the formation of a stable nucleus followed by attachment of monomer units\(^{34}\). While there appears to be a stable nucleus, the trimer, the further growth in most cases does not involve the incorporation of individual octapods, even though monomers are abundant and show extensive Brownian motion (Supplementary Note 2 and Supplementary Fig. 16). Instead, the stable nucleus grows primarily by attachment of other supercritical units, all of which are mobile in the solution. Attachment is facilitated by a considerable bending flexibility of the chains, which, for instance, allows long chains near the membrane to reach into the bulk liquid to capture a diffusing segment (Fig. 3a, Supplementary Fig. 10 and Supplementary Movie 4).

**Statistical mechanical model.** We constructed a model to probe the physical origin of the striking suppression of dimers and the prevalence of trimers as the shortest chain of interlocked octapods in solution. Using the measured chain-length distribution and other characteristics identified uniquely by \textit{in situ} microscopy, the model provides insight into the interactions underlying the self-assembly process. In equilibrium, the probability of finding a chain of length \(n\) can be determined from the grand canonical distribution function:

\[
C_n \propto \int d\Gamma e^{-\beta[H - \mu n]}
\]  

(1)

Here the chemical potential of octapods is determined by the monomer concentration, \(C_1\), as \(\mu = kT \ln C_1\); \(H\) is the interaction Hamiltonian of the system, \(\beta = 1/kT\) and \(d\Gamma\) represents an integration over internal degrees of freedom of the chain, that is, positions and orientations of \(n - 1\) octapods. If we neglect physical binding between the octapods (that is, assume \(H = 0\), but exclude their mutual overlap), the confinement of a single octapod within a cage made by two of its neighbours can be represented as a factor \(v\). This factor has the meaning of an
other. This leads to the following distribution function:

\[ C_n \sim (C_1 v)^{n-1} \left( 1 + \frac{\delta}{\Delta} e^{\epsilon/kT} \right)^{Z_n} \]  

An alternative, more detailed derivation of this result is presented in Supplementary Note 3. \( Z_n \) is the total number of contacts between the octapods that can be independently formed within the chain. This parameter is of crucial importance for understanding the observed chain statistics, in particular the substantial suppression of dimers compared with longer chains. We assume the maximum number of contacts that can be made between nearest neighbours to be 4. This implies that a tighter interlocking of two octapods with eight mutual contacts is not sterically allowed, presumably because of the geometry of their octahedral cores. This is consistent with the experimental observations (see below). In addition to the interactions with its nearest neighbours, it is assumed that fluctuations in the chain allow an octapod to create up to four contacts with any of its next-nearest neighbours. This consideration sets an upper bound to the number of contacts in a chain: \( Z_n \leq 4(n-1) + 4(n-2) = 8n - 12 \). However, this is not the only limitation. Each octapod has six degrees of freedom: three translational and three rotational. This means that for trimers \( (n=3) \) the number of possible contacts (12) is exactly equal to the number of internal degrees of freedom of the chain, \( 6(n-1) \). For dimers \( (n=2) \), the number of contacts is less than the number of degrees of freedom (4 and 6, respectively), while for chains longer than \( (n \geq 3) \), the situation is opposite. The maximally connected structure with \( Z_n = 8n - 12 \) would be over-constrained, and can only exist if the shapes are identical and symmetric to a very high precision. Any imperfection would lead to a loss of some of the contacts. We therefore postulate that the number of internal degrees of freedom sets another bound on the value of \( Z_n \), that is,

\[ Z_n = \min(8n - 12, 6(n-1)) \]  

This model can successfully describe the observed chain statistics, including the suppression of dimers. In fact, its major predictions are very robust with respect to the choice of the model parameters. For \( n \geq 3 \), \( Z_n = 6(n-1) \), that is, the overall distribution function is proportional to an exponential, \( C_n \propto p^{n-1} \), where \( p=(C_1 v)^{1+\delta \sigma /\Delta} \). For \( n=2 \), \( Z_n=4 \), that is, dimers are suppressed by a factor \((C_1 v)^{1/3}\).

As far as the specific parameters are concerned, the characteristic radius \( \Delta \) of the octapod is set to \( \sim 30 \) nm, half the pod length; \( \Delta \approx 15 \) nm was estimated as the difference between the apparent interparticle distance in the chain.
(50 nm) and its minimal value allowed geometrically (35 nm). The estimated average concentration of free octapods in the area in which self-assembly takes place is \( c_1 \sim 10^{-6} \text{ M} \sim 10^{-6} \text{ nm}^{-3} \), so that \( c_1 \nu \sim c_1 \Delta^6/R^3 \) is of order \( 10^{-3} \).

**Discussion**

Once the geometrical parameters of the model are fixed, the only free parameter of the model is the energy per contact, \( \epsilon \). The value of the energy that gives the best fit to the experimental data is \( \epsilon = 2.7kT \) (Fig. 3c), approximately twice the energy expected for a pure van der Waals interaction between two crossed pods\(^{21}\). The difference may be due to effects of inter-digitation of the ligands. The robustness of our model can be illustrated by the fact that changing \( c_1 \nu \) by a factor of 2 leads to a correction to the binding strength \( \epsilon \) of 0.1\( kT \), and to a relative change of the dimer fraction of only 25%.

Additional molecular dynamics simulations also show that a pure van der Waals interaction is not sufficient to induce assembly (see Supplementary Note 4, Supplementary Methods and Supplementary Figs 17–19). Adding a short-range attraction does lead to chain formation.

In our model the assembly is driven not only by the energy gained because of binding. The fact that each contact fluctuates between bound and unbound states results in an additional entropic-free energy contribution \(-6kT \ln(1 + \frac{1}{2} e^{\epsilon/kT}) \approx -2kT\) per particle that stabilizes the chain. A final piece of evidence that supports the proposed mechanism stems from measurements of the octapod spacing in chains, determined in situ to avoid uncertainties due to capillary forces that may affect ex situ measurements of the lattice constant of dried or vitrified assemblies. The observed next-nearest neighbour octapod distance in solution (\( \approx 100 \text{ nm} \), Fig. 4b) is in fact greater than the one needed for physical contact between four tips of the two octapods (\( \approx 85 \text{ nm} \), close to the value found ex situ in vacuum (Fig. 4c) or vitrified solvent\(^{21}\)). This distance is however sufficient to make up to two simultaneous contacts upon some rotation. In this way, the system can achieve the required value of \( Z_n \) (6 per particle) without paying an excessive entropic penalty for the extra confinement. The loose packing in solution also rationalizes characteristics important to chain growth, such as the facile addition and removal of segments and the bending of chains in tight radii, involved in capturing chain segments at later growth stages.

By imaging the self-assembly of branched nanocrystals with monomer resolution in solution, our experiments have pointed out a novel avenue for studying key aspects of self-assembly, such as the mechanism of formation and growth of ordered nanocrystal arrays and the interparticle spacing in solution. On the basis of characteristics obtained from in situ microscopy, a statistical mechanics model could be built that established the relative importance of van der Waals and entropic forces and determined the strength of the particle–particle interaction. A similar approach can be applied to other systems, such as spherical or polyhedral particles that arrange in two-dimensional or 3D assemblies, binary or more complex nanocrystal mixtures, or the folding and assembly of suitably tagged proteins. Once cells are developed that allow for controlled mixing of different liquids, external stimuli (for example, changes in PH, addition of...
co-solvents or depletants and so on.) may be used to actively change the assembly process while observing the outcome in real time.

Methods

Materials preparation. CdSe/CdS octad-shaped nanocrystals were synthesized following a procedure based on the growth of CdS seeds on cuboctahedral CdSe seeds that are prepared after a cation exchange process from Cu2+/Cd2+ seeds that are prepared after a cation exchange process from Cu2+/Cd2+ seeds. Briefly, a reaction flask was loaded with 120 mg of CdO and various surfactants (6 g of trioctylphosphine oxide, 160 mg of hexylphosphonic acid and 580 mg of octadecylphosphonic acid). The flask was kept under vacuum at 150 °C for 2 hours. The temperature was increased to 250 °C and 1.6 g of trioctylphosphine was injected. After the recovery of the temperature, an aliquot of previously prepared Cu2+/Cd2+ nanocrystals with a concentration of 0.3 × 10−6 M was quickly injected in the flask after the addition of 160.5 mg of trioctylphosphine solution. The reaction was run for 10 min and cooled down to the room temperature. After several washing steps with an anti-solvent, the final product was dispersed in 5 ml of toluene.

In situ liquid-cell STEM experiments. The liquid-cell experiments were carried out in a dedicated specimen holder (Hummingbird Scientific) using micro-fabricated liquid cells, consisting of two 30-nm-thick SiN membranes with 50 μm × 50 μm window area supported by Si frames. The spacing between the windows was controlled using 200 and 300 nm polystyrene beads or 100 and 200 nm SiO2 spacers. STEM imaging was performed in a FEI Titan 80–300 environmental Cs image corrected microscope operated at 300 KV. Low-loss electron energy loss spectra (EELS) were acquired using a Gatan Efinia spectrometer with an entrance aperture semi-angle of 5 mrad. The weighted average of the ratio of the thickness and the inelastic mean free path for the toluene and the SiN membrane (each 30 nm thick) was determined from low-loss EELS, and the toluene thickness was calculated from it according to ref. 35 (Supplementary Figs 3,5 and 6). Typically, ~1 μl of the octad-containing solution with an initial concentration of particles of 10−8 M was introduced in the liquid cell. The holder was inserted in the microscope immediately after loading of the cell. The time delay between loading of the solution and initiating the observations was ~10–20 min. STEM imaging was performed with ~2 Å probe size and ~0.2–0.3 nA beam current, measured in vacuum before introduction of the liquid cell. Time-lapse series of STEM images were acquired at several positions along the cell window, and at all positions the assembly of octapods was observed in real time. The results of the observations at two different areas are shown in Supplementary Movies 1 and 8. For Supplementary Movies 1–7 time-lapse STEM images of the assembly of the octapods were recorded with frame interval of 1 s and 3.96 μs dwell time/pixel. The conditions for the acquisition of STEM images were electron dose rate of 1.35 e− Å−2 s−1, electron dose per image of 1.35 e− Å−2, total electron dose for the movie (204 frames) of 275.4 e− Å−2. The Supplementary Movies 1–7 are played at 20 frames per second. The original STEM images are shown in Supplementary Fig. 1. The STEM images in which the octapods appear dark on a light background have been inverted (in the program ImageJ) to facilitate visual perception and analysis. Supplementary Movie 8 is a series of time-lapse images recorded at a frame interval of 9 s.

Image contrast in in situ liquid STEM of octad assemblies. The use of a focused probe in STEM, whose focal plane coincides with one of the membranes (for example, the top membrane) of the liquid cell, implies a limited 3D imaging capability. As an octapod chain transits from the bulk solution towards the membrane (Supplementary Fig. 2a, top), it initially appears with soft contrast that progressively turns into dark contrast (Supplementary Fig. 2a, bottom). Electron beam exposure generally induces octapods and chains to move from the interior of the solution towards the SiN membrane, possibly as a result of a beam-induced charging of the membrane.
