We present a scanning magnetic force sensor based on an individual magnet-tipped GaAs nanowire (NW) grown by molecular beam epitaxy. Its magnetic tip consists of a final segment of single-crystal MnAs formed by sequential crystallization of the liquid Ga catalyst droplet. We characterize the mechanical and magnetic properties of such NWs by measuring their flexural mechanical response in an applied magnetic field. Comparison with numerical simulations allows the identification of their equilibrium magnetization configurations, which in some cases include magnetic vortices. To determine a NW’s performance as a magnetic scanning probe, we measure its response to the field profile of a lithographically patterned current-carrying wire. The NWs’ tiny tips and their high force sensitivity make them promising for imaging weak magnetic field patterns on the nanometer-scale, as required for mapping mesoscopic transport and spin textures or in nanometer-scale magnetic resonance.

A key component in any force microscopy is the force sensor. This device consists of a mechanical transducer, used to convert force into displacement, and an optical or electrical displacement detector. In magnetic force microscopy (MFM), mass-produced ‘top-down’ Si cantilevers with sharp tips coated by a magnetic material have been the standard for years. Under ideal conditions, state-of-the-art MFM can reach spatial resolutions down to 10 nm [1], though more typically around 100 nm. These conventional cantilevers are well-suited for the measurement of the large forces and force gradients produced by strongly magnetized samples.

The advent of nanostructures such as nanowires (NWs) and carbon nanotubes (CNTs) grown by ‘bottom-up’ techniques has given researchers access to much smaller mechanical force transducers than ever before. This reduction in size implies both a better force sensitivity [2] and – potentially – a finer spatial resolution [3]. Sensitivity to small forces provides the ability to detect weak magnetic fields and therefore to image subtle magnetic patterns; tiny concentrated magnetic tips have the potential to achieve nanometer-scale spatial resolution, while also reducing the invasiveness of the tip on the sample under investigation. Such improvements are crucial for imaging nanometer-scale magnetization textures such as domain walls, vortices and skyrmions [4–7]; superconducting vortices [8, 9]; mesoscopic transport in two-dimensional systems [10]; and small ensembles of nuclear spins [11–14].

Recent experiments have demonstrated the use of single NWs and CNTs as sensitive scanning force sensors [15–18]. When clamped on one end and arranged in the pendulum geometry, i.e. with their long axes perpendicular to the sample surface to prevent snapping into contact, they probe both the size and direction of weak tip-sample forces. NWs have been demonstrated to maintain excellent force sensitivities around 1 nN/√Hz near sample surfaces (< 100 nm), due to extremely low non-contact friction [19]. As a result, NW sensors have been used as transducers in force-detected nanometer-scale magnetic resonance imaging [20] and in the measurement of optical and electrical forces [15–17]. Nevertheless, the integration of a magnetic tip onto a NW transducer – and therefore the demonstration of NW MFM – has presented a significant practical challenge.

Here, we demonstrate such MFM transducers using individual GaAs NWs with integrated single-crystal MnAs tips, grown by molecular beam epitaxy (MBE). By monitoring each NW’s flexural motion in an applied magnetic field, we determine its mechanical and magnetic properties. We determine the equilibrium magnetization configurations of each tip by comparing its magnetic response with micromagnetic simulations. In order to determine the sensitivity and resolution of the NWs as MFM transducers, we use them as scanning probes in the pendulum geometry. By analyzing their response to the magnetic field produced by a lithographically patterned current-carrying wire, we find that the MnAs tips can be approximated as nearly perfect magnetic dipoles. The thermally-limited sensitivity of a typical NW to magnetic field gradients is found to be 11 nT/(m√Hz), which corresponds to the gradient produced by 61 nA/√Hz through the wire at a tip-sample spacing of 250 nm.

The GaAs NWs are grown on a Si(111) substrate by MBE using a self-catalyzed Ga-assisted growth method [21]. A substrate temperature of 600 °C allows the growth of high quality crystalline NWs, which are typically 18±1 µm long with a hexagonal cross-section of 225±15 nm in diameter. In order to terminate the growth with a magnetic tip, the liquid Ga catalyst droplet at the top of the NW is heavily alloyed by a Mn flux. Then, to initiate its crystallization, it is exposed to an As background pressure for 30 minutes. Under such conditions, the droplet undergoes a sequential precipitation: first, the Ga is preferentially consumed to build pure GaAs; next, the remaining Mn crystallizes in the form of MnAs.
It has been shown by high-resolution transmission electron microscopy that this growth process leads to the formation of a well-defined hexagonal $\alpha$-MnAs wurzite crystal at the tip of a predominantly wurzite GaAs NW, with an epitaxial relationship [0001]MnAs || [0001]GaAs along the NW-axis [22]. As reported for bulk MnAs, the tip is in a hexagonal ferromagnetic $\alpha$-phase up to the Curie temperature of about 313 K, above which it undergoes a structural phase transition into an orthorhombic $\beta$-phase [23]. MnAs crystals are characterized by a strong magnetocrystalline anisotropy with $K = -1 \times 10^6$ J m$^{-3}$ along the $c$-axis (hard axis) [24]. As a result, the magnetization of the tip will tend to lie in the plane (easy plane) orthogonal to the $c$-axis, which – in general – is coincident with the NW growth direction $\mathbf{\hat{n}}$.

The sample chip is cleaved directly from the Si wafer used for the NWs’ growth. Using a micromanipulator under an optical microscope, we remove excess NWs to leave a single row of isolated and vertically standing NWs in proximity of the cleaved edge (Fig 1(b)). The chip is then loaded into a custom-built scanning probe microscope, which includes piezoelectric positioners to align a single NW within the focus of a fiber-coupled optical interferometer used to detect its mechanical motion [25]. A second set of piezoelectric positioners enables the approach and scanning of the NW transducer over a sample of interest, as shown schematically in Fig. 1(a). The microscope is enclosed in a high-vacuum chamber at a pressure of $10^{-7}$ mbar and inserted in the bore of a superconducting magnet at the bottom of a liquid $^4$He bath cryostat. All the data presented here have been measured at a temperature $T = 4.2$ K. In order to characterize the magnetic properties of the NWs, we apply a magnetic field $\mathbf{B}$ up to $\pm 8$ T approximately parallel to $\mathbf{\hat{n}}$.

For the purposes of this work, we restrict our attention to the two fundamental flexural eigenmodes of the NWs, which oscillate along orthogonal directions and are shown schematically in Fig. 1(a). The coupling between the NW and the thermal bath results in a Langevin force equally driving both mechanical modes. Fig. 1(c) shows a calibrated power spectral density (PSD) of the NW displacement noise, where the two resonance peaks correspond to the two orthogonally polarized modes. Such a measurement shows the projection of the modes’ 2D thermal motion along the interferometric measurement axis $\mathbf{\hat{m}}$, determined by the position of the NW in the optical waist (see Methods). Typical resonance frequencies range from 500 to 700 kHz with quality factors between $2 \times 10^3$ and $5 \times 10^4$. For each NW, the doublet modes are completely decoupled by a frequency splitting $\delta$ of several hundred times the peak linewidth. In fact, it has been shown that even very small ($< 1\%$) cross-sectional or clamping asymmetries can split the modes by several linewidths [26]. Nevertheless, the quality factors of the doublet modes differ by less than $1\%$. The spring constants extracted from fits to the PSD for each flexural mode are on the order of $10$ mN/m, yielding mechanical dissipations and thermally-limited force sensitivities down to $50$ pg/s and few $aN/\sqrt{Hz}$, respectively.

We exploit this high mechanical sensitivity to probe the magnetization of each individual magnetic tip. As in dynamic cantilever magnetometry (DCM) [27–29], we can extract magnetic properties of each MnAs tip from the mechanical response of the NW to a uniform external magnetic field $\mathbf{B}$. In such a field, the resonance frequency of each orthogonal flexural mode $f_i$ ($i = 1, 2$) is modified by the curvature of the system’s magnetic energy $E_m$ with respect to rotations $\theta_i$ about its oscillation axis. The resulting frequency shift $\Delta f_i = f_i - f_{0i}$, where $f_{0i}$ is the resonance frequency at $B = 0$, is given by

$$\Delta f_i = \frac{f_{0i}}{2k_i l_e^2} \left. \frac{\partial^2 E_m}{\partial \theta_i^2} \right|_{\theta_i = 0},$$

where $k_i$ is the NW’s spring constant and $l_e$ is its effective length [30, 31].

We perform measurements of $\Delta f_i(B)$ on several NWs by recording the thermal displacement PSD of their doublet modes as a function of $B$. For nearly all investigated
NWs (11 out of 12), $\Delta f_i(B)$ is negative for all applied fields (e.g. Fig. 2(a) and Fig. 3(a)). In general, negative values of $\Delta f_i$ correspond to a local maximum in $E_m(\theta)$ with respect to $\theta_i$. This behavior is consistent with $\mathbf{B}$ being aligned along the magnetic hard axis of the MnAs tip, which should be along the NW growth-axis. Fig. 2(a) shows a particularly ideal magnetic response, in which the high-field frequency shift of both modes asymptotically approaches the same negative value. This behavior indicates a MnAs particle with a hard axis along $\mathbf{n}$ and no preferred easy axis in the $r_1r_2$-plane.

In order to gain a deeper understanding of the DCM signal, we carry out simulations of the MnAs tips using Mumax3 [32], which employs the Landau-Lifshitz-Gilbert micromagnetic formalism using finite-difference discretization. For each value of $B$, the simulations determine the equilibrium magnetization configuration of the MnAs particle and the corresponding values of $\Delta f_i$ (see Methods). The geometry of the MnAs tip is estimated by SEM and set within the simulation with respect to the two oscillation directions of the modes $\mathbf{r}_1, \mathbf{r}_2$ and the NW axis $\mathbf{n} = \mathbf{r}_1 \times \mathbf{r}_2$.

The DCM response of the MnAs tip measured in Fig. 2(a) and shown in the inset is simulated by approximating its shape as a half-ellipsoid, with dimensions given in the inset of Fig. 2(b) and its caption. The excellent agreement between the simulated and measured $\Delta f_i(B)$, both plotted in Fig. 2(b), allows us to precisely determine the direction of the magnetic hard axis. As expected, this axis is found to be nearly along $\mathbf{n}$: just $\theta_K = 2.5^\circ$ away from $\mathbf{n}$ and $\phi_K = 19.5^\circ$ from $\mathbf{r}_1$. Furthermore, as shown in Fig. 2(c), the simulations relate a specific magnetization configuration to each value of $B$. In this particular case, a stable vortex configuration in the easy plane is seen to enter (exit) from the edge in correspondence with the abrupt discontinuities in the eigenmodes’ frequencies around $+2T$ ($-2T$). Between these two fields, the vortex core moves from one side to the other, inducing several discontinuities in $\Delta f_i(B)$. The smoothness of the measured frequency shifts around $B = 0 \ T$ indicates pinning...
of the vortex and is well-reproduced in the simulation by the introduction of two sites of pinned magnetization (see Supplementary Information)).

Most measured NWs present DCM curves as shown in Fig. 3(a) (10 out of 12). Despite the similarity of these curves to those shown in Fig. 2(a), no sharp discontinuity is observed upon sweeping B down from saturation (forward applied field). Furthermore, the high-field frequency shift of both modes does not asymptotically approach the same negative value as in Fig. 2(a). Both of these effects can be explained by taking into account magnetic shape anisotropy in the MnAs tips. Despite the nearly perfect symmetry of NW1’s tip, most of the crystallized MnAs droplets are asymmetric in the $r_1r_2$-plane. This asymmetry introduces an effective magnetic easy axis in the $r_1r_2$-plane. In fact, the measured $\Delta f_i(B)$ shown in Fig. 3(a) are well-reproduced by a simulation that takes into account the geometry of NW2’s MnAs tip as observed by SEM. While small refinements in the microscopic geometry, which often cannot be confirmed by the SEM, affect how well the simulation matches every detail of the measured $\Delta f_i(b)$ (see Supplementary Information), the precise orientation of the hard axis and the direction of the effective shape anisotropy in the $r_1r_2$-plane sensitively determine the curves’ overall features (e.g. their high field asymptotes and shape).

In general, simulations show that shape anisotropy restricts the field range for a stable magnetic vortex to reverse applied field. In small forward applied field and in remanence, the magnetization evolves through a configuration with a net magnetic dipole in the $r_1r_2$-plane. Only upon application of a reverse field, does this configuration smoothly transform into a vortex, resulting – for NW2 – in a subtle dip in $\Delta f_i(B)$ around $B = -0.3$ T. At a reverse field close to $B = -2$ T, an abrupt jump indicates the vortex’s exit and the appearance of a single-domain state, which eventually turns toward B. This analysis indicates that NW2’s tip – as well as the majority of the MnAs tips – present a dipole-like remanent configuration pointing in the $r_1r_2$-plane, rather than vortex-like configuration with a core pointing along $\hat{n}$, as in NW1. Such remanent magnetic dipoles have been already observed by MFM in similar tips [22, 33].

In rare cases (1 of 12), such as the one reported for NW3 in Fig. 3(b), we measure mostly positive $\Delta f_i(B)$ with different high-field asymptotes for each eigenmode. This behavior indicates a MnAs particle, whose hard axis points approximately in the $r_1r_2$-plane. In fact, the features of the measured $\Delta f_i(B)$ in Fig. 2(b) are reproduced by a simulation considering a nearly symmetric half-ellipsoid with a hard-axis lying $\theta_K = 72^\circ$ from $\hat{n}$ and $\phi_K = 6.3^\circ$ from $\hat{r}_1$. These data are clear evidence that crystallization of the liquid droplet can occasionally occur along a direction far off of the NW growth axis.

In order to test the behavior of these NWs as scanning magnetic sensors, we approach a typical one (NW2) to a current-carrying Au wire patterned on a SiO$_2$ substrate, as described in Fig. 4(a). Once in the vicinity of the wire constriction, the NW’s two modes are excited by the Biot-Savart field $\mathbf{B}_{\text{AC}}$ resulting from an oscillating drive current $I = I_1 \sin(2\pi f_1 t) + I_2 \sin(2\pi f_2 t)$, where $I_1 = I_2 = 50\mu$A. Single 10 μm-long line scans are acquired by moving the NW across the wire at the fixed tip-sample spacing $d_z = 250$ nm, while both the resonant frequencies $f_i$ and displacement amplitudes $r_i$ are tracked using two phase-locked loops. The corresponding values of the force
driving each mode at resonance are then calculated as $F_i = q_i k_i / Q_i$ (see Supplementary Information).

Using an approach similar to that used to calibrate MFM tips [34–36], we model the force exerted by a well-known magnetic field profile on the magnetic tip by using the so-called point-probe approximation. This approximation models the complex magnetization distribution of the tip as an effective monopole moment $q_0$ and a dipole moment $m$ located at a distance $d$ from the tip apex (the monopole contribution compensates for the non-negligible spatial extent of the tip). The magnetic force acting on each mode is then given by $D_i = q_0 B_{AC} \cdot \hat{r}_i + \nabla (m \cdot B_{AC}) \cdot \hat{r}_i$. Moreover, we also consider the magnetic torque $\tau = m \times B_{AC}$ generated at the tip, which results in a torsion and/or bending of the NW depending on its orientation. Although this contribution is negligible in conventional MFM, the NW modes’ short length makes their spatial extent significant in this case. As a result, $\tau$ contributes to the NW motion with variances $\sigma^2_\tau \approx \sigma^2_\tau \approx S_{r_2}(\omega_2) \times BW_{\text{neq}}$, where $S_{r_2}(\omega)$ is a fit to the second mode’s thermal PSD shown in Fig. 1 (c), $\omega_2$ is the resonant angular frequency of the second mode, and $BW_{\text{neq}}$ is the lock-in’s equivalent noise bandwidth.

We characterize the NW magnetic response at $B = -5T$ and $B = 0$. In the high field case shown in Fig. 4(b), a fit of the two driving forces is obtained with an effective dipole $m$ nearly along the NW’s easy plane and is not completely saturated. In the fit, the effective dipole contribution is dominant and mostly orthogonal to the NW axis $\hat{n}$ with $|m| = 0.73M_s V$. The direction of $m$ is closely related to the torque contribution making the fit particularly sensitive to the value of $\phi_m$. Spurious electrostatic driving of the NW modes is negligible.

The NWs’ high force sensitivity combined with highly concentrated and strongly magnetized dipole-like tips give them an exquisite sensitivity to magnetic field gradients. In order to quantify this sensitivity, we restrict our attention to the second mode (red) of NW2, positioning it at the point of maximal response over the wire at $d_2 = 250$ nm and $B = 0$ T (i.e. $y = 4.5$ pm on Fig. 4(c)). The displacement signal $r_2$ is measured with a lock-in amplifier while decreasing the driving current $I = I_2 \sin(2\pi f_2 t)$. The sweeps plotted in Fig. 5(a) and (b) show the expected linear response as well as a wide dynamic range. In Fig. 5(b), we focus on the low-current regime, showing both the in-phase $X$ (signal+noise) and quadrature $Y$ (noise) response. By simple linear regression, we find a transduction factor $\beta = 0.22$ nm/µA, which results in both $X$ and $Y$ being Gaussian and fully ascribable to the NW’s thermal motion with variances $\sigma^2_\tau \approx \sigma^2_\tau \approx S_{r_2}(\omega_2) \times BW_{\text{neq}}$, where $S_{r_2}(\omega)$ is a fit to the second mode’s thermal PSD shown in Fig. 1 (c), $\omega_2$ is the resonant angular frequency of the second mode, and $BW_{\text{neq}}$ is the lock-in’s equivalent noise bandwidth. As shown in Fig. 5 (c) for $Y$, the mode’s thermal PSD is assumed constant around its value at resonance $S_{r_2}(\omega) = 4k_B T Q_2 / \omega_2$. Due to the narrow measurement bandwidth, therefore, the NW's sec-

Figure 5. NW sensitivity to a resonant current drive at a distance of 250 nm. (a) Plot of the oscillation amplitude $r_2$ for each value of the current amplitude $I_2$, both quantities are root mean squared. (b) Plot of in-phase response to the drive $(X)$ and quadrature signal $(Y)$ for a finer current sweep from $I_2 = 1$ µA to $I_2 = 1$ nA. The lock-in demodulator low-pass filter noise equivalent bandwidth was set to $BW_{\text{neq}} = 0.156$ Hz and each point was averaged for 2.5 sec. Both signals are linearly fit (dark dashed lines). The intersection (light blue cross) between the linearly fit signal $\bar{X}$ and the quadrature signal $\bar{Y}$ for each value of the current amplitude $I_2$, describes the displacement sensitivity (dashed purple line). The intersection (light blue cross) between the linearly fit signal $\bar{X}$ and the quadrature signal $\bar{Y}$ for each value of the current amplitude $I_2$, describes the displacement sensitivity (dashed purple line). The intersection (light blue cross) between the linearly fit signal $\bar{X}$ and the quadrature signal $\bar{Y}$ for each value of the current amplitude $I_2$, describes the displacement sensitivity (dashed purple line). The intersection (light blue cross) between the linearly fit signal $\bar{X}$ and the quadrature signal $\bar{Y}$ for each value of the current amplitude $I_2$, describes the displacement sensitivity (dashed purple line).
ond mode has a thermally-limited displacement sensitivity of \( \sqrt{S_r(\omega)} = 19 \text{ pm}/\sqrt{\text{Hz}} \), equivalent to a force sensitivity of \( \sqrt{S_r(\omega)k_2/Q_2} = 3.5 \text{ aN}/\sqrt{\text{Hz}} \). Given the measured current transduction factor \( \beta \) at the working tip-sample spacing \( d_z = 250 \text{ nm} \), we obtain a sensitivity to current flowing through the wire of \( 61 \text{ nA}/\sqrt{\text{Hz}} \).

Such sensitivity to electrical current compares favorably to that of other microscopies capable of imaging current through Biot-Savart fields, including scanning Hall microscopy, magneto-optic microscopy, scanning SQUID microscopy, microwave impedance microscopy, and scanning nitrogen-vacancy magnetometry [37, 38]. Because of the dipole-like character of the MnAs tip, this transduction of current into displacement is dominated by the effect of the time-varying magnetic field gradient generated by the current: \( F_i \approx \nabla(\mathbf{m} \cdot \mathbf{B}_{AC}) \cdot \hat{r}_i = \mathbf{m} \cdot \nabla(\mathbf{B}_{AC} \cdot \hat{r}_i) \). Although the torque resulting from the time-varying magnetic field produces an effective force, \( T_i \), as seen in Figs. 4 (b) and (c), this term is typically secondary. Therefore, from COMSOL simulations of the field produced by current flowing through the wire, we find this current sensitivity to correspond to a sensitivity to magnetic field gradient of \( 11 \text{ mT}/(\text{mV}/\text{Hz}) \) at the position of the tip’s effective point probe, i.e. \( d_z + d = 350 \text{ nm} \) above the surface. Having quantified the NW’s response to other magnetic fields, we can calculate its sensitivity to other magnetic field sources, including a magnetic moment (dipole field), a superconducting vortex (monopole field), or an infinitely long and thin line of current [37]. In particular, we expect a moment sensitivity of \( 54 \frac{\mu_B}{\sqrt{\text{Hz}}} \), a flux sensitivity of \( 1.3 \frac{\mu\Phi_0}{\sqrt{\text{Hz}}} \), and line-current sensitivity of \( 9 \frac{\text{nA}}{\sqrt{\text{Hz}}} \). These values show the capability of magnet-tipped NWs as probes of weak magnetic field patterns and the huge potential for improvement if tips sizes and tip-sample spacings can be reduced (see Supplementary Information).

In addition to improved sensitivity, NW MFM provides other potential advantages compared to conventional MFM. First, scanning in the pendulum geometry with the NW oscillating in the plane of the sample has the characteristics of lateral MFM. This technique, which is realized with the torsional mode of a conventional cantilever, distinguishes itself from the more commonly used tapping-mode MFM in its ability to produce magnetic images devoid of spurious topography-related contrast and in a demonstrated improvement in lateral spatial resolution of up to 15\% [39]. Second, the nanometer-scale magnetic particle at the apex of the NW force sensor minimizes the size of the MFM tip, allowing for optimal spatial resolution and minimal perturbation of the investigated sample.

The prospect of increased sensitivity and resolution, combined with few restrictions on operating temperature, make NW MFM ideally suited to investigate nanometer-scale spin textures, skyrmions, superconducting and magnetic vortices, as well as ensembles of electronic or nuclear spins. Non-invasive magnetic tips may also open opportunities to study current flow in 2D materials and topological insulators. The ability of a NW sensor to map all in-plane spatial force derivatives [16, 17] should provide fine detail of stray field profiles above magnetic and current carrying samples, in turn providing detailed information on the underlying phenomena. Directional measurements of dissipation may also prove useful for visualizing domain walls and other regions of inhomogeneous magnetization. As shown by Grutter et al., dissipation contrast, which maps the energy transfer between the tip and the sample, strongly depends on the sample’s nanometer-scale magnetic structure [40].

**METHODS**

**Interferometric detection:** The linearly polarized light emitted by a laser diode with wavelength \( \lambda = 1553 \text{ nm} \) is directly coupled to a polarization maintaining optical fiber, sent through the 5% transmission arm of a 95:5 fiber-optic coupler, collimated and focused on the NW by a pair of lenses. This confocal reflection microscopy setup, analogous to the one described in [41], focuses light to a minimum beam waist of \( w_0 = 1.65 \mu m \) (see Supplementary Information). The light incident on the NW has a power of 25 \( \mu W \) and is polarized along its long axis. Light scattered back by the NW interferes with light reflected by the fiber’s cleaved end, resulting in a low-finesse Fabry-Perot interferometer. A fast photo-receiver monitors variations in the intensity of reflected light, allowing for the sensitive detection of NW motion. The interferometric signal is proportional to the projection of the NW’s motion along the direction of the interference pattern’s gradient \( \hat{\mathbf{m}} \). The magnitude of this gradient at the position of the NW determines the interferometer’s transduction factor. By positioning the NW within the optical waist or changing the wavelength of the laser, it is possible to measure the motion projected along arbitrary directions. For displacement measurements presented in this work, NWs have been positioned on the optical axis \( \hat{\mathbf{y}} \) in order to have \( \hat{\mathbf{m}} \parallel \hat{\mathbf{y}} \) (see Supplementary Information).

**Numerical simulations:** Micromagnetic simulations are carried out with Mumax3. We set the saturation magnetization \( \mu_0 M_s = 1.005 \text{ T} \), the exchange stiffness constant \( A = 10 \text{ pJ/m} \), and the magnetocrystalline anisotropy \( K = -1.2 \times 10^6 \text{ J/m}^3 \) in correspondence with the values reported for MnAs in the literature [24, 42]. We model the geometry of each MnAs magnetic tip based on observations made in a SEM. Space is discretized into cubic mesh elements, which are 5 nm on a side, which corresponds to the dipolar exchange length of the material \( l_{xx} = \sqrt{2A/(\mu_0 M_s^2)} \). The validity of this discretization is confirmed by comparing the results of a few representative simulations with simulations using much smaller...
memes. *Mumax3* determines the equilibrium magnetization configuration for each external field value by numerically solving the Landau-Lifshitz-Gilbert equation. Since the microscopic processes in a MnAs tip are expected to be much faster than the NW resonance frequencies, the magnetization of the tip is assumed to be in its equilibrium orientation throughout the cantilever oscillation. The calculation also yields the total magnetic energy $E_m$ corresponding to each configuration. In order to simulate $\Delta f_i$, we numerically calculate the second derivatives of $E_m$ with respect to $\theta_i$ found in (1). At each field, we calculate $E_m$ at the equilibrium angles $\theta_i = 0$ and at small deviations from equilibrium $\theta_i = \pm \delta \theta_i$. For small $\delta \theta_i$, the second derivative can be approximated by a finite difference: \[ \left. \frac{\partial^2 E_m}{\partial \theta_i^2} \right|_{\theta=0} \approx \frac{E_m(\delta \theta_i + 2E_m(0)) + E_m(-\delta \theta_i)}{2}. \] By setting $f_0$, $k_i$, and $l_i$ to their measured values, we then arrive at the $\Delta f_i$ corresponding to each magnetization configuration in the numerically calculated field dependence.

**SUPPLEMENTARY INFORMATION**

Supplementary information is available for download at [RossiSupp.pdf](https://example.com/RossiSupp.pdf). This file includes sections discussing: the optical setup for NW motion detection; displacement calibration and force estimation; micromagnetic simulations of NW magnetometry; simulated $B_{AC}$ profile; sensitivity to different types of magnetic field sources.

Movies of the simulated magnetization reversal for the presented MnAs tips are available at NW1.avi, NW2.avi, NW3.avi.

**ACKNOWLEDGEMENTS**

We thank Sascha Martin and his team in the machine shop of the Physics Department at the University of Basel for help building the measurement system. We thank Lorenzo Ceccarelli for help with magnetic field simulations and Prof. Ilaria Zardo for suggesting the collaboration.
