Abstract—Small basestations (SBs) equipped with caching units have potential to handle the unprecedented demand growth in heterogeneous networks. Through low-rate, backhaul connections with the backbone, SBs can prefetch popular files during off-peak traffic hours, and service them to the edge at peak periods. To intelligently prefetch, each SB must learn what and when to cache, while taking into account SB memory limitations, the massive number of available contents, the unknown popularity profiles, as well as the space-time popularity dynamics of user file requests. In this work, local and global Markov processes model user requests, and a reinforcement learning (RL) framework is put forth for finding the optimal caching policy when the transition probabilities involved are unknown. Joint consideration of global and local popularity demands along with cache-refreshing costs allow for a simple, yet practical asynchronous caching approach. The novel RL-based caching relies on a Q-learning algorithm to implement the optimal policy in an online fashion, thus enabling the cache control unit at the SB to learn, track, and possibly adapt to the underlying dynamics. To endow the algorithm with scalability, a linear function approximation of the proposed Q-learning scheme is introduced, offering faster convergence as well as reduced complexity and memory requirements. Numerical tests corroborate the merits of the proposed approach in various realistic settings.

Index Terms—Caching, dynamic popularity profile, reinforcement learning, Markov decision process (MDP), Q-learning.

I. INTRODUCTION

The advent of smart phones, tablets, mobile routers, and a massive number of devices connected through the Internet of Things (IoT) have led to an unprecedented growth in data traffic. Increased number of users trending towards video streams, web browsing, social networking and online gaming, have urged providers to pursue new service technologies that offer acceptable quality of experience (QoE). One such technology entails network densification by deploying small picocells and femto-cells, each serviced by a low-power, low-coverage, small basestation (SB). In this infrastructure, referred to as heterogeneous network (HetNet), SBs are connected to the backbone by a cheap ‘backhaul’ link. While boosting the network density by substantial reuse of scarce resources, e.g., frequency, the HetNet architecture is restrained by its low-rate, unreliable, and relatively slow backhaul links [1].

During peak traffic periods specially when electricity prices are also high, weak backhaul links can easily become congested—an effect lowering the QoE for end users. One approach to mitigate this limitation is to shift the excess load from peak periods to off-peak periods. Caching realizes this shift by fetching the “anticipated” popular contents, e.g., reusable video streams, during off-peak periods, storing this data in SBs equipped with memory units, and reusing them during peak traffic hours [2]–[4]. In order to utilize the caching capacity intelligently, a content-agnostic SB must rely on available observations to learn what and when to cache. To this end, machine learning tools can provide 5G cellular networks with efficient caching, in which a “smart” caching control unit (CCU) can learn, track, and possibly adapt to the space-time popularities of reusable contents [2], [5].

Prior work. Existing efforts in 5G caching have focused on enabling SBs to learn unknown time-invariant content popularity profiles, and cache the most popular ones accordingly. A multi-armed bandit approach is reported in [6], where a reward is received when user requests are served via cache; see also [7] for a distributed, coded, and convexified reformulation. A belief propagation-based approach for distributed and collaborative caching is also investigated in [8]. Beyond [6], [7], and [8] that deal with deterministic caching, [9] and [10] introduce probabilistic alternatives. Caching, routing and video encoding are jointly pursued in [11] with users having different QoE requirements. However, a limiting assumption in [6]–[11] pertains to space-time invariant modeling of popularities, which can only serve as a crude approximation for real-world requests. Indeed, temporal dynamics of local requests are prevalent due to user mobility, as well as emergence of new contents, or, aging of older ones. To accommodate dynamics, Ornstein-Uhlenbeck processes and Poisson shot noise models are utilized in [12] and [13], respectively, while context- and trend-aware caching approaches are investigated in [14] and [15].

Another practical consideration for 5G caching is driven by the fact that a relatively small number of users request contents during a caching period. This along with the small size of cells can challenge SBs from estimating accurately the underlying content popularities. To address this issue, a transfer-learning approach is advocated in [16], [17] and [13], to improve the time-invariant popularity profile estimates by leveraging prior information obtained from a surrogate (source) domain, such as social networks.

Finally, recent studies have investigated the role of coding for enhancing performance in cache-enabled networks [18]–[20]; see also [21], [22], and [23], where device-to-device...
“structureless” caching approaches are envisioned.

**Contributions.** The present paper introduces a novel approach to account for space-time popularity of user requests by casting the caching task in a reinforcement learning (RL) framework. The CCU of the local SB is equipped with storage and processing units for solving the emerging RL optimization in an online fashion. Adopting a Markov model for the popularity dynamics, a Q-learning caching algorithm is developed to learn the optimal policy even when the underlying transition probabilities are unknown.

Given the geographical and temporal variability of cellular traffic, global popularity profiles may not always be representative of local demands. To capture this, the proposed framework entails estimation of the popularity profiles both at the local as well as at the global scale. Specifically, each SB estimates its local vector of popularity profiles based on limited observations, and transmits it to the network operator, where an estimate of the global profile is obtained by aggregating the local ones. The estimate of the global popularity vector is then sent back to the SBs. The SBs can adjust the cost (reward) to trade-off tracking global trends versus serving local requests.

To obtain a scalable caching scheme, a novel approximation of the proposed Q-learning algorithm is also developed. Furthermore, despite the stationarity assumption on the popularity Markov models, proper selection of stepsizes broadens the scope of the proposed algorithms for tracking demands even in non-stationary settings.

The rest of this paper is organized as follows. Section II introduces the system model and problem formulation, and Section III presents the optimal Q-learning algorithm. Linear function approximation, and the resultant scalable solver are the subjects of Section IV, while Section V presents numerical tests, and Section VI concludes the paper.

**Notation.** Lower- (upper-) case boldface letters denote column vectors (matrices), whose \((i,j)\)-th entry is denoted by \([\cdot]_{i,j}\). Calligraphic symbols are reserved for sets, while \(\dagger\) stands for transposition.

II. MODELING AND PROBLEM STATEMENT

Consider a local section of a HetNet with a single SB connected to the backbone network through a low-bandwidth, high-delay, unreliable backhaul link. Suppose further that the SB is equipped with \(M\) units to store contents (files) that are assumed for simplicity to have unit size; see Fig. 1. Caching will be carried out in a slotted fashion over slots \(t = 1,2,\ldots\), where at the beginning of each slot \(t\), the CCU-enabled SB selects “intelligently” \(M\) files from the total of \(F\) available ones at the backbone, and prefetches them for possible use in subsequent slots. The slots may not be of equal length, as the starting times may be set a priori, for example at 3 AM, 11 AM, or 4 PM, when the network load is low; or, slot intervals may be dictated to CCU by the network operator on the fly. Generally, a slot starts when the network is at an off-peak period, and its duration coincides with the peak traffic time when pertinent costs of serving users are high.

During slot \(t\), each user locally requests a subset of files from the set \(\mathcal{F} := \{1,2,\ldots,F\}\). If a requested file has been stored in the cache, it will be simply served locally, thus incurring (almost) zero cost. Conversely, if the requested file is not available in the cache, the SB must fetch it from the cloud through its cheap backhaul link, thus incurring a considerable cost due to possible electricity price surges, processing cost, or the sizable delay resulting in low QoE and user dissatisfaction. The CCU wishes to intelligently select the cache contents so that costly services from the cloud be avoided as often as possible.

Let \(a(t) \in \mathcal{A}\) denote the \(F \times 1\) binary caching action vector at slot \(t\), where \(\mathcal{A} := \{a|a \in \{0,1\}^F, a^{\top}1 = M\}\) is the set of all feasible actions; that is, \([a(t)]_f = 1\) indicates that file \(f\) is cached for the duration of slot \(t\), and \([a(t)]_f = 0\) otherwise.

Depending on the received requests from locally connected users, the CCU computes the \(F \times 1\)-vector of local popularity profile \(p_L(t)\) per slot \(t\), whose \(f\)-th entry indicates the expected local demand for file \(f\), defined as

\[
[p_L(t)]_f := \frac{\text{Number of local requests for } f \text{ at slot } t}{\text{Number of all local requests at slot } t}.
\]

Similarly, suppose that the backbone network estimates the \(F \times 1\) global popularity profile vector \(p_G(t)\), and transmits it to all CCUs.

Having observed the local and global user requests by the end of slot \(t\), our overall system state is

\[
s(t) := [p_G(t), p_L(t), a^{\top}(t)]^{\top}. \tag{1}
\]

Being at slot \(t - 1\), our objective is to leverage historical observations of states, \(\{s(\tau)\}_{\tau=0}^{t-1}\), and pertinent costs in order to learn the optimal policy for the next slot, namely \(a^*(t)\). Explicit expression of the incurred costs, and analytical formulation of the objective will be elaborated in the ensuing subsections.

A. Cost functions and caching strategies

Efficiency of a caching strategy will be measured by how well it utilizes the available storage of the local SB to keep the most popular files, versus how often local user requests are met via fetching through the more expensive backhaul link. The

---

**Fig. 1:** Local section of a HetNet.
overall cost incurred will be modeled as the superposition of three types of costs.

The first type \(c_{1,t}\) corresponds to the cost of refreshing the cache contents. In its general form, \(c_{1,t}(\cdot)\) is a function of the upcoming action \(a(t)\), and available contents at the cache according to current caching action \(a(t-1)\), where the subscript \(t\) captures the possibility of a time-varying cost for refreshing the cache. A reasonable choice of \(c_{1,t}(\cdot)\) is

\[
c_{1,t}(a(t), a(t-1)) := \lambda_{1,t} a^T(t) [1 - a(t-1)]
\]

which upon recalling that the action vectors \(a(t-1)\) and \(a(t)\) have binary \(\{0,1\}\) entries, implies that \(c_{1,t}\) counts the number of those files to be fetched and cached prior to slot \(t\), which were not stored according to action \(a(t-1)\).

The second type of cost is incurred during the operational phase of slot \(t\) to satisfy user requests. With \(c_{2,t}(s(t))\) denoting this type of cost, a prudent choice must: i) penalize requests for files already cached much less than requests for files not stored; and, ii) be a non-decreasing function of popularities \([p_L]_f\). Here for simplicity, we assume that the transmission cost of cached files is relatively negligible, and choose

\[
c_{2,t}(s(t)) := \lambda_{2,t} [1 - a(t)]^T p_L(t) \tag{2b}
\]

which solely penalizes the non-cached files in descending order of their local popularities.

The third type of cost captures the “mismatch” between caching action \(a(t)\), and the global popularity profile \(p_G(t)\). Indeed, it is reasonable to consider the global popularity of files as an acceptable representative of what the local profiles will look like in the near future; thus, keeping the caching action close to \(p_G(t)\) may reduce future possible costs. Note also that a relatively small number of local requests may only provide a crude estimate of local popularities, while the global popularity profile can serve as side information in tracking the evolution of content popularities over the network. This has prompted the advocacy of transfer learning approaches, where content popularities in a surrogate domain are utilized for improving estimates of popularity; see, e.g., [16] and [17]. However, this approach is limited by the degree the surrogate (source) domain, e.g., Facebook or Twitter, is a good representative of the target domain requests. When it is not, techniques will misguide caching decisions, while imposing excess processing overhead to the network operator or to the SB.

To account for this issue, we introduce the third type of cost as

\[
c_{3,t}(s(t)) := \lambda_{3,t} [1 - a(t)]^T p_G(t) \tag{2c}
\]

penalizing the files not cached according to the global popularity profile \(p_G(\cdot)\) provided by the network operator, thus promoting adaptation of caching policies close to global demand trends.

All in all, upon taking action \(a(t)\) at slot \(t\), the aggregate cost conditioned on the popularity vectors revealed, can be expressed as (cf. \(2a\)–\(2c\))

\[
C_t \left( s(t-1), a(t); p_G(t), p_L(t) \right) := c_{1,t}(a(t), a(t-1)) + c_{2,t}(s(t)) + c_{3,t}(s(t))
\]

\[
= \lambda_{1,t} a^T(t) (1 - a(t-1)) + \lambda_{2,t} (1 - a(t))^T p_L(t) + \lambda_{3,t} (1 - a(t))^T p_G(t).
\]

Weights \(\lambda_{1,t}\), \(\lambda_{2,t}\), and \(\lambda_{3,t}\) control the relative significance of the corresponding summands, whose tuning influences the optimal caching policy at the CCU. As asserted earlier, the cache-refreshing cost at off-peak periods is considered to be less than fetching the contents during slots, which justifies the choice \(\lambda_{1,t} \ll \lambda_{3,t}\). In addition, setting \(\lambda_{3,t} \ll \lambda_{2,t}\) is of interest when the local popularity profiles are of acceptable accuracy, or, if tracking local popularities is of higher importance. In particular, setting \(\lambda_{3,t} = 0\) corresponds to the special case where the caching cost is decoupled from the global popularity profile evolution. On the other hand, setting \(\lambda_{2,t} \ll \lambda_{3,t}\) is desirable in networks where globally popular files are of high importance, for instance when users have high mobility and may change SBs rapidly, or, when a few local requests prevent the SB from estimating accurately the local popularity profiles. Fig. 2 depicts the evolution of popularity and action vectors along with the aggregate conditional costs across slots.

**Remark 1.** As with slot sizes, proper selection of \(\lambda_{1,t}, \lambda_{2,t}\), and \(\lambda_{3,t}\) is a design choice. Depending on how centralized or decentralized the network operation is desired to be, these parameters may be selected autonomously by the CCUs or provided by the network operator in a centralized fashion. However, the overall approach requires the network service provider and the SBs to inter-operate by exchanging relevant information. On the one hand, estimating global popularities requires SBs to transmit their locally obtained \(p_L(t)\) to the network operator at the end of each slot. On the other hand, the network operator informs the CCUs of the global popularity \(p_G(t)\), and possibly weights \(\lambda_{1,t}, \lambda_{2,t}\), and \(\lambda_{3,t}\). By providing the network operator with means of parameter selection, a “master-slave” hierarchy emerges, which enables the network operator (master) to influence SBs (slaves) caching decisions, leading to a centrally controlled adjustment of caching policies. Interestingly, these few bytes of information exchanges occur once per slot and at off-peak instances, thus imposing negligible overhead to the system, while enabling a simple,
yet practical and powerful optimal semi-distributed caching process; see Fig. 3.

B. Popularity profile dynamics

As depicted in Fig. 3, we will model user requests (and thus popularities) at both global and local scales using Markov chains. Specifically, global popularity profiles will be assumed generated by an underlying Markov process with $|P_G|$ states collected in the set $P_G := \{p_G^1, \ldots, p_G^{P_G}\}$, and likewise for the set of all local popularity profiles $P_L := \{p_L^1, \ldots, p_L^{P_L}\}$. Although $P_G$ and $P_L$ are known, the underlying transition probabilities of the two Markov processes are considered unknown.

Given $P_G$ and $P_L$, as well as feasible caching decisions in set $A$, the overall set of states in the network is

$$\mathcal{S} := \{s|s = [p_G^T, p_L^T, a^T]^T, p_G \in P_G, p_L \in P_L, a \in A\}.$$ 

The lack of knowledge on transition probabilities of the underlying Markov chains motivates well our ensuing RL-based approach, where the learner seeks the optimal policy by interactively making sequential decisions, and observing the corresponding costs. The caching task is formulated in the following subsection, and an efficient solver is developed to cope with the “curse of dimensionality” typically emerging with RL problems [24].

C. Reinforcement learning formulation

As shown in Fig. 2, the CCU takes caching action $a(t)$, at the beginning of slot $t$, and by the end of slot $t$, the profiles $p_G(t)$ and $p_L(t)$ become available, so that the system state is updated to $s(t)$, and the conditional cost $C_t\left(s(t), a(t)|p_G(t), p_L(t)\right)$ is revealed. Given the random nature of user requests locally and globally, $C_t$ in [3] is a random variable with mean

$$C_t\left(s(t-1), a(t)\right) = \mathbb{E}_{p_G(t), p_L(t)}[C_t\left(s(t-1), a(t)|p_G(t), p_L(t)\right)]$$

where the expectation is taken with respect to (wrt) $p_L(t)$ and $p_G(t)$, while the weights are selected as $\lambda_1 = \lambda_1, \lambda_2 = \lambda_2$, and $\lambda_3 = \lambda_3$ for simplicity.

Let us now define the policy function $\pi : \mathcal{S} \rightarrow \mathcal{A}$, which maps any state $s \in \mathcal{S}$ to the action set. Under policy $\pi(\cdot)$, for the current state $s(t)$, caching is carried out via action $a(t+1) = \pi(s(t))$ dictating what files to be stored for the $(t+1)$-st slot. Caching performance is measured through the so-called state value function

$$V_\pi (s(t)) := \lim_{T \to \infty} \mathbb{E}\left[\sum_{t=0}^{T} \gamma^{t-t}C_t(s(t), \pi(s(t)))\right]$$

which is the total average cost incurred over an infinite time horizon, with future terms discounted by factor $\gamma \in [0,1)$. Since taking action $a(t)$ influences the SB state in future slots, future costs are always affected by past and present actions. Discount factor $\gamma$ captures this effect, whose tuning trades off current versus future costs. Moreover, $\gamma$ also accounts for modeling uncertainties, as well as imperfections, or dynamics. For instance, if there is ambiguity about future costs, or if the system changes very fast, setting $\gamma$ to a small value enables one to prioritize current costs, whereas in a stationary setting one may prefer to demote future costs through a larger $\gamma$.

The objective of this paper is to find the optimal policy $\pi^*$ such that the average cost of any state $s$ is minimized (cf. [5])

$$\pi^* = \arg\min_{\pi \in \Pi} V_\pi (s), \forall s \in \mathcal{S}$$

where $\Pi$ denotes the set of all feasible policies.

The optimization in (6) is a sequential decision making problem. In the ensuing section, we present optimality conditions (known as Bellman equations) for our problem, and introduce a Q-learning approach for solving (6).

III. Optimality conditions

Bellman equations, also known as dynamic programming equations, provide necessary conditions for optimality of a policy in a sequential decision making problem. Being at the $(t-1)$st slot, let $[P^\pi]_{ss'\cdot}$ denote the transition probability of going from the current state $s$ to the next state $s'$ under action $a$; that is,

$$[P^\pi]_{ss'\cdot} := \Pr\left\{s(t) = s'|s(t-1) = s, \pi(s(t-1)) = a\right\}.$$ 

Bellman equations express the state value function by [5] in a recursive fashion as [24, pg. 47]

$$V_\pi (s) = C_t(s, \pi(s)) + \sum_{s' \in \mathcal{S}} [P^\pi(s)]_{ss'} V_\pi (s'), \forall s, s'$$

which amounts to the superposition of $C_t$ plus a discounted version of future state value functions under a given policy $\pi$. 

Fig. 3: Schematic of network structure with required communications in SBs, and with the network operator.
Specifically, after dropping the current slot index \( t - 1 \) and indicating with prime quantities of the next slot \( t \), \( C \) in (4) can be written as

\[
\overline{C}(s, \pi(s)) = \sum_{s':=[p_G, p'_L, \alpha] \in S} [P^{\pi(s)}_{ss'}] C\left(s, \pi(s)\right) p_G(p'_L, \alpha)
\]

where \( C\left(s, \pi(s)\right) \) is found as in (3). It turns out that, with \([P^\pi_{ss'}]\) given \(v_s, s'\), one can readily obtain \( \{v_s(s), v_s\}\) by solving (7), and eventually the optimal policy \( \pi^* \) in (4) using the so-called policy iteration algorithm (24 pg. 79). To outline how this algorithm works in our context, define the state-action value function that we will rely on under policy \( \pi^* \) as

\[
Q^*_{\pi^*}(s, a) := \overline{C}(s, a') + \gamma \sum_{s' \in S} [P^\pi_{ss'}] V_{\pi}(s').
\]

Commonly referred to as the “Q-function,” \( Q^*_{\pi}(s, \alpha) \) basically captures the expected cost of taking action \( \alpha \) when the system is in state \( s \), followed by the discounted value of the future states, provided that the future actions are taken according to policy \( \pi^* \).

In our setting, the policy iteration algorithm initialized with \( \pi_0 \), proceeds with the following updates at the \( i \)-th iteration.

- **Policy evaluation**: Determine \( V_{\pi_i}(s) \) for all states \( s \in S \) under the current (fixed) policy \( \pi_{i+1} \), by solving the system of linear equations in (7) \( \forall s \).

- **Policy update**: Update the policy using

\[
\pi_{i+1}(s) := \text{arg} \max_{\alpha} Q_{\pi_{i+1}}(s, \alpha), \quad \forall s \in S.
\]

The policy evaluation step is of complexity \( O(|S|^3) \), since it requires matrix inversion for solving the linear system of equations in (7). Furthermore, given \( V_{\pi_i}(s) \) \( \forall s \), the complexity of the policy update step is \( O(|A||S|^2) \), since the Q-values must be updated per state-action pair, each subject to \(|S| \) operations; see also (3). Thus, the per iteration complexity of the policy iteration algorithm is \( O(|S|^3 + |A||S|^2) \). Iterations proceed until convergence, i.e., \( \pi_{i+1}(s) = \pi_i(s), \forall s \in S \).

Clearly, the policy iteration algorithm relies on knowing \([P^\pi_{ss'}]\), which is typically not available in practice. This motivates the use of adaptive dynamic programming (ADP) that learn \([P^\pi_{ss'}]\) for all \( s, s' \in S \), and \( \alpha \in A \), as iterations proceed ([25 pg. 834]). Unfortunately, ADP algorithms are often very slow and impractical, as they must estimate \(|S|^2 \times |A| \) probabilities. In contrast, the Q-learning algorithm elaborated next finds the optimal \( \pi^* \) as well as \( V_{\pi^*}(s) \), while circumventing the need to estimate \([P^\pi_{ss'}]\), \( \forall s, s' \); see e.g., [24 pg. 140].

### A. Optimal caching via Q-learning

Q-learning is an online RL scheme to jointly infer the optimal policy \( \pi^* \) and estimate the optimal state-action value function \( Q^*_{\pi}(s, a') := Q_{\pi^*}(s, a') \forall s, a' \). Utilizing (7) for the optimal policy \( \pi^* \), it can be shown that ([24 pg. 62])

\[
\pi^*(s) = \arg \min_{\alpha} Q^*(s, \alpha), \quad \forall s \in S.
\]

#### Algorithm 1 Caching via Q-learning at CCU

**Initialize** \( s(0) \) randomly and \( Q_0(s, a) = 0 \forall s, a \)

for \( t = 1, 2, \ldots \) do

Take action \( a(t) \) chosen probabilistically by

\[
a(t) = \begin{cases} 
\arg \min_{\alpha} \hat{Q}_{t-1}(s(t-1), \alpha) & \text{w.p. } 1 - \epsilon_t \\
\text{random } a \in A & \text{w.p. } \epsilon_t
\end{cases}
\]

\( P_L(t) \) and \( P_G(t) \) are revealed based on user requests

Set \( s(t) := [P_G^T(t), P_L^T(t), a(t)^T]^T \)

Incur cost \( C\left(s(t-1), a(t)|p_G(t), p_L(t)\right) \)

Update

\[
\hat{Q}_t(s(t-1), a(t)) = (1 - \beta_t)\hat{Q}_{t-1}(s(t-1), a(t)) + \beta_t \left[ C\left(s(t-1), a(t)|p_G(t), p_L(t)\right) + \gamma \min_{\alpha} \hat{Q}_{t-1}(s(t), \alpha) \right]
\]

end for

The Q-function and \( V(\cdot) \) under \( \pi^* \) are related by

\[
V^*(s) := V_{\pi^*}(s) = \min_{\alpha} Q^*(s, \alpha)
\]

which in turn yields

\[
Q^*(s, a') = \overline{C}(s, a') + \gamma \sum_{s' \in S} [P^\pi_{ss'}] \min_{\alpha \in A} Q^*(s', \alpha).
\]

#### Capitalizing on the optimality conditions ([9], [11]), an online Q-learning scheme for caching is listed under Alg. 1. In this algorithm, the agent updates its estimated \( \hat{Q}(s(t-1), a(t)) \) as \( C\left(s(t-1), a(t)|p_G(t), p_L(t)\right) \) is observed. That is, given \( s(t-1), Q \)-learning takes action \( a(t) \), and upon observing \( s(t) \), it incurs cost \( C\left(s(t-1), a(t)|p_G(t), p_L(t)\right) \).

Based on the instantaneous error

\[
\varepsilon(s(t-1), a(t)) := \frac{1}{2} \left( C\left(s(t-1), a(t)\right) + \gamma \min_{\alpha} \hat{Q}(s(t), \alpha) - \hat{Q}(s(t-1), a(t)) \right)^2
\]

the Q-function is updated using stochastic gradient descent as

\[
\hat{Q}_t(s(t-1), a(t)) = (1 - \beta_t)\hat{Q}_{t-1}(s(t-1), a(t)) + \beta_t \left[ C\left(s(t-1), a(t)|p_G(t), p_L(t)\right) + \gamma \min_{\alpha} \hat{Q}_{t-1}(s(t), \alpha) \right]
\]

while keeping the rest of the entries in \( \hat{Q}_{t}(\cdot, \cdot) \) unchanged.

Regarding convergence of the Q-learning algorithm, a necessary condition ensuring \( \hat{Q}_t(\cdot, \cdot) \to Q^*(\cdot, \cdot) \), is that all state-action pairs must be continuously updated. Under this and the usual stochastic approximation conditions that will be specified later, \( \hat{Q}_t(\cdot, \cdot) \) converges to \( Q^*(\cdot, \cdot) \) with probability 1; see [29] for a detailed description.

To meet the requirement for continuous updates, Q-learning utilizes a probabilistic exploration-exploitation approach to selecting actions. At slot \( t \), exploitation happens with probability \( 1 - \epsilon_t \) through the action \( a(t) = \arg \min_{\alpha \in A} Q_{t-1}(s(t -
where \( Q \), \( \gamma \), \( \beta \), and \( \alpha \) are parameters. The exploration happens with probability \( \epsilon \) through a random action \( a \in \mathcal{A} \). Parameter \( \epsilon \) trades off exploration for exploitation, and its proper selection guarantees a necessary condition for convergence. During initial iterations or when the CCU observes considerable shifts in content popularities, setting \( \epsilon \) high promotes exploration in order to learn the underlying dynamics. On the other hand, in stationary settings and once "enough" observations are made, small values of \( \epsilon \) promote exploiting the learned \( Q_{t-1}(\cdot, \cdot) \) by taking the estimated optimal action \( \arg \min_a Q_{t-1}(s(t), a) \).

Regarding stochastic approximation conditions, the stepsize sequence \( \{\beta_t\}_{t=1}^{\infty} \) must obey \( \sum_{t=1}^{\infty} \beta_t = \infty \) and \( \sum_{t=1}^{\infty} \beta_t^2 < \infty \) \([26]\), both of which are satisfied by e.g., \( \beta_t = 1/t \). However, with a selection of constant stepsize \( \beta = \beta \), the mean-square error (MSE) of \( Q_{t+1}(\cdot, \cdot) \) is bounded as (cf. \([26]\))

\[
E \left[ \left\| \hat{Q}_{t+1} - Q^* \right\|^2 \right| P \leq \varphi_1(\beta) + \varphi_2(\hat{Q}_0) \exp(-2\beta t) \tag{13}
\]

where \( \varphi_1(\beta) \) is a positive and increasing function of \( \beta \), while the second term denotes the initialization error, which decays exponentially as the iterations proceed.

Although selection of a constant stepsize prevents the algorithm from exact convergence to \( Q^* \) in stationary settings, it enables CCU adaptation to the underlying non-stationary Markov processes in dynamic scenarios. Furthermore, the optimal policy in practice can be obtained from the Q-function values before convergence is achieved \([24] \text{ pg. 79} \).

However, the main practical limitation of the Q-learning algorithm is its slow convergence, which is a consequence of independent updates of the Q-function values. Indeed, Q-function values are related, and leveraging these relationships can lead to multiple updates per observation as well as faster convergence. In the ensuing section, the structure of the problem at hand will be exploited to develop a linear function approximation of the Q-function, which in turn will endow our algorithm not only with fast convergence, but also with scalability.

### IV. SCALABLE CACHING

Despite simplicity of the updates as well as optimality guarantees of the Q-learning algorithm, its applicability over real networks faces practical challenges. Specifically, the Q-table is of size \(|P_G||P_L||A|^2\), where \(|A| = (F)\) encompasses all possible selections of \( M \) from \( F \) files. Thus, the Q-table size grows prohibitively with \( F \); rendering convergence of the table entries, as well as the policy iterates unacceptably slow. Furthermore, action selection in \( \min_{a \in \mathcal{A}} Q(s, a) \) entails an expensive exhaustive search over the feasible action set \( \mathcal{A} \).

Linear function approximation is a popular scheme for rendering Q-learning applicable to real-world settings \([25], [27], [28]\). A linear approximation for \( Q(s, a) \) in our setup is inspired by the additive form of the instantaneous costs in (3). Specifically, we propose to approximate \( Q(s, a) \) as

\[
Q(s, a') \approx Q_G(s, a') + Q_L(s, a') + Q_R(s, a') \tag{14}
\]

where \( Q_G, Q_L, \) and \( Q_R \) correspond to global and local popularity mismatch, and cache-refreshing costs, respectively.

Recall that the state vector \( s \) consists of three subvectors, namely \( s := [p_G^T, p_L^T, a^T] \). Corresponding to the global popularity subvector, our first term of the approximation in (14) is

\[
Q_G(s, a') := \sum_{i=1}^{P_G} \sum_{f=1}^{F} \theta_{i,f}^G \mathbb{1}_{\{p_G = p_G^i\}} \mathbb{1}_{\{a'_{f} = 0\}} \tag{15}
\]

where the sums are over all possible global popularity profiles as well as files, and the indicator function \( \mathbb{1}_{\cdot} \) takes value 1 if its argument holds, and 0 otherwise; while \( \theta_{i,f}^G \) captures the average "overall" cost if the system is in global state \( p_G^i \), and the CCU decides not to cache the \( f \)th content. By defining the \( |P_G| \times |F| \) matrix with \((i, f)\)-th entry \( \Theta^G_{i,f} := \theta_{i,f}^G \), one can rewrite (15) as

\[
Q_G(s, a') = \delta^G(p_G) \Theta^G (1 - a') \tag{16}
\]

where

\[
\delta^G(p_G) := \left[ \delta(p_G - p_G^1), \ldots, \delta(p_G - p_G^{|P_G|}) \right]^T .
\]

Similarly, we advocated the second summand in the approximation (14) to be

\[
Q_L(s, a') := \sum_{i=1}^{P_L} \sum_{f=1}^{F} \theta_{i,f}^L \mathbb{1}_{\{p_L = p_L^i\}} \mathbb{1}_{\{a'_{f} = 0\}}
= \delta^L(p_L) \Theta^L (1 - a') \tag{17}
\]

where \( \Theta^L \) modeling the average overall cost for not caching file \( f \) when the local popularity is in state \( p_L^i \).

Finally, our third summand in (14) corresponds to the cache-refreshing cost

\[
Q_R(s, a') := \sum_{f=1}^{F} \theta^R \mathbb{1}_{\{a'_{f} = 1\}} \mathbb{1}_{\{a'_{f} = 0\}}
= \theta^R a^T (1 - a)
= \theta^R \mathbb{1}_{\{a^T (1 - a) + a^T \mathbb{1} - a^T \mathbb{1}\}}
= \theta^R \mathbb{1}_{\{1 - a'}
\]

where \( \theta^R \) models average cache-refreshing cost per content. The constraint \( a^T 1 = a^T = M \) is utilized to factor out the term \( 1 - a' \), which will become useful later.

Upon defining the set of parameters \( \Lambda := \{\Theta^G, \Theta^L, \theta^a\} \), the Q-function is readily approximated (cf. (14))

\[
\hat{Q}_\Lambda (s, a') := \left( \delta^G(p_G) \Theta^G + \delta^L(p_L) \Theta^L + \theta^R a^T \right) (1 - a') \tag{19}
\]

Thus, the original task of learning \( |P_G||P_L||A|^2 \) parameters in Alg. 1 is now reduced to learning \( \Lambda \) containing \(||P_G| + |P_L|| |F| + 1\) parameters.
obtained using stochastic gradient descent iterations as scalable scheme is three-fold.

Algorithm 2 Scalable Q-learning

Initialize $s(0)$ randomly, $\hat{\Theta}_0^G = 0$, $\hat{\Theta}_0^L = 0$, $\hat{\theta}_0^R = 0$, and thus $\hat{\psi}(s) = 0$

for $t = 1, 2, \ldots \ $ do
  Take action $a(t)$ chosen probabilistically by
  
  $a(t) = \begin{cases} 
  M \text{ best files via } \hat{\psi}(s(t-1)) \text{ w.p. } 1 - \epsilon_t \\
  \text{random } a \in A \text{ w.p. } \epsilon_t 
  \end{cases}$

  $p_G(t)$ and $p_L(t)$ are revealed based on user requests
  $p_G(t)$ and $p_L(t)$ are revealed based on user requests

  Set $s(t) := [p_G(t), p_L^T(t), a(t)^T]^T$
  Incur cost $C\left(s(t-1), a(t), p_G(t), p_L(t)\right)$
  Find $\hat{\varepsilon}(s(t-1), a(t))$
  Update $\hat{\Theta}_t^G$, $\hat{\Theta}_t^L$ and $\hat{\theta}_t^R$ based on (21)-(23)

end for

A. Learning $\Lambda$

Given the current parameter estimates $\{\hat{\Theta}^G_{t-1}, \hat{\Theta}^L_{t-1}, \hat{\theta}^R_{t-1}\}$ at the end of slot $t$, the instantaneous error is given by

$$\hat{\varepsilon}(s(t-1), a(t)) := \frac{1}{2} \left(C(s(t-1), a(t)) + \gamma \min_{a'} \hat{Q}_{\Lambda_{t-1}}(s(t-1), a') - \hat{Q}_{\Lambda_{t-1}}(s(t-1), a(t))\right)^2.$$ 

Based on this error form, the parameter update rules are obtained using stochastic gradient descent iterations as

$$\hat{\Theta}_t^G = \hat{\Theta}_{t-1}^G - \alpha_G \nabla_{\Theta} \hat{\varepsilon}(s(t-1), a(t)),$$

$$\hat{\Theta}_t^L = \hat{\Theta}_{t-1}^L - \alpha_L \nabla_{\Theta} \hat{\varepsilon}(s(t-1), a(t)),$$

and

$$\hat{\theta}_t^R = \hat{\theta}_{t-1}^R - \alpha_R \nabla_{\theta} \hat{\varepsilon}(s(t-1), a(t)).$$

The pseudocode for this scalable approximation of the Q-learning scheme is tabulated in Alg. 2. The upshot of this scalable scheme is three-fold:

- The exhaustive search in $\min_a Q(s, a)$ required in exploitation; and also in the error evaluation (20), is circumvented. Specifically, it holds that (cf. (19))

$$\min_a Q(s, a) \approx \min_a \psi^\top(s) (1 - a') = \max_a \psi^\top(s) a'$$

where

$$\psi(s) := \delta_G^T(p_G)\Theta^G + \delta_L^T(p_L)\Theta^L + \theta^R a^\top.$$

The solution of (24) is readily given by $[a]_{i+} = 1$ for $i = 1, \ldots, M$, and $[a]_{i-} = 0$ for $i > M$, where $[\psi(s)]_{i+} \leq \cdots \leq [\psi(s)]_{i-}$ are sorted entries of $\psi(s)$.

Remark 2. In the model of Sec. II-B, the state-space cardinality of the popularity vectors is finite. These vectors can be viewed as centroids of quantization regions partitioning a state space of infinite cardinality. Clearly, such a partitioning inherently bears a complexity-accuracy trade off, motivating optimal designs to achieve a desirable accuracy for a given affordable complexity. This is one of our future research directions for the problem at hand.

Simulation based evaluation of the proposed algorithms for RL-based caching is now in order.

V. Numerical tests

In this section, performance of the proposed Q-learning algorithm and its scalable approximation is tested. To compare the proposed algorithms with the optimal offline caching policy, we first simulated a small network with $F = 10$ contents, and caching capacity $M = 2$ at the local SB. Global popularity profile is modeled by a two-state Markov chain with states $p^G_1$ and $p^G_2$ that are drawn from Zipf distributions having parameters $\eta^G_1 = 1$ and $\eta^G_2 = 1.5$, respectively [29]; see also Fig. [4] That is, for state $i \in \{1, 2\}$, the $F$ contents are assigned a random ordering of popularities, and then sorted accordingly in a descending order. Given this ordering and the Zipf distribution parameter $\eta^G_i$, the popularity of the $f$-th content is set to

$$p^G_i = \frac{1}{\sum_{i=1}^{F} f^G_i} \quad \text{for } i = 1, 2$$

where the summation normalizes the components to follow a valid probability mass function, while $\eta^G_i \geq 0$ controls the skewness of popularities. Specifically, $\eta^G_i = 0$ yields a uniform spread of popularity among contents, while a large value of $\eta^G_i$ generates more skewed popularities. Furthermore, state transition probabilities of the Markov chain modeling global popularity profiles are

$$P^G := \begin{bmatrix} p^G_1 & p^G_2 \\ p^G_2 & p^G_2 \end{bmatrix} = \begin{bmatrix} 0.8 & 0.2 \\ 0.75 & 0.25 \end{bmatrix}.$$ 

Similarly, local popularities are modeled by a two-state Markov chain, with states $p^L_1$ and $p^L_2$ whose entries are drawn from Zipf distributions with parameters $\eta^L_i = 0.7$ and
The transition probabilities of the local popularity Markov chain are

\[ P_L := \begin{bmatrix} p_{11}^L & p_{12}^L \\ p_{21}^L & p_{22}^L \end{bmatrix} = \begin{bmatrix} 0.6 & 0.4 \\ 0.2 & 0.8 \end{bmatrix}. \]

Caching performance is assessed under two cost-parameter settings: (s1) \( \lambda_1 = 10, \lambda_2 = 600, \lambda_3 = 1000 \); and, (s2) \( \lambda_1 = 600, \lambda_2 = 10, \lambda_3 = 1000 \). For both (s1) and (s2), the optimal offline caching policy is found by utilizing the policy iteration with known transition probabilities. In addition, Q-learning in Alg. 1 and its scalable approximation converge to that of the optimal offline policy. As anticipated, even via Q-learning, and through its scalable approximation convergence is achieved. As the plot demonstrates, the exact Q-learning Alg. 1 exhibits slower convergence, whereas just a few iterations suffice for the scalable Alg. 2 to converge to the optimal solution, thanks to the reduced dimension of the problem as well as the multiple updates that can be afforded per iteration.

Having established the accuracy and efficiency of the Alg. 2, we next simulated a larger network with \( F = 1,000 \) available files, and a cache capacity of \( M = 10 \), giving rise to a total of \( \binom{1000}{10} \approx 2 \times 10^{23} \) feasible caching actions. In addition, we set the local and global popularity Markov chains to have \( |P_L| = 40 \) and \( |P_G| = 50 \) states, for which the underlying state transition probabilities are drawn randomly, and Zipf parameters are drawn uniformly over the interval \((2, 4)\).

Fig. 6 plots the performance of Alg. 2 under (s5) \( \lambda_1 = 100, \lambda_2 = 20, \lambda_3 = 20 \), (s6) \( \lambda_1 = 0, \lambda_2 = 0, \lambda_3 = 1,000 \), and (s7) \( \lambda_1 = 0, \lambda_2 = 1,000, \lambda_3 = 600 \). Exploration-exploitation parameter is set to \( \epsilon_t = 1 \) for \( t = 1, 2, \ldots, 5,000 \), in order to greedily explore the entire state-action space in initial iterations, and \( \epsilon_t = 1 / \text{iteration index} \) for \( t > 5,000 \). Finding the optimal offline policy in (s6) and (s7) requires prohibitively sizable memory as well as extremely high computational complexity, and it is thus unaffordable for this network. However, having large cache-refreshing cost with \( \lambda_1 \gg \lambda_2, \lambda_3 \) in (s5) forces the optimal caching policy to freeze its cache contents, making the optimal caching policy predictable in this setting. Despite the very limited storage capacity, of \( 10/1,000 = 0.01 \) of available files, utilization of RL-enabled caching offers a considerable reduction in incurred costs, while the proposed approximated Q-learning endows the approach with scalability and light-weight updates.

VI. CONCLUSIONS

The present work addresses caching in 5G cellular networks, where space-time popularity of requested files is modeled via local and global Markov chains. By considering local and global popularity mismatches as well as cache-refreshing costs, 5G caching is cast as a reinforcement-learning task. A Q-learning algorithm is developed for finding the optimal
caching policy in an online fashion, and its linear approximation is provided to offer scalability over large networks. The novel RL-based caching offers an asynchronous and semi-distributed caching scheme, where adaptive tuning of parameters can readily bring about policy adjustments to space-time variability of file requests via light-weight updates.
