ABSTRACT

The most important complications of Philadelphia-negative (non BCR-ABL) myeloproliferative neoplasms (MPNs) are vascular events. Our aim was to evaluate the effects of single nucleotide polymorphisms (SNPs), platelet glycoproteins (GPs) (Ia/IIa, Ibα, IIb/IIIa and VI), von Willebrand factor (vWF), coagulation factor VII (FVII), β-fibrinogen, and the risk of thrombosis in patients with non BCR-ABL MPNs at the Lithuanian University of Health Sciences, Kaunas, Lithuania. Genotyping was done for 108 patients. The TT genotype of the GPla/IIa c.807C>T polymorphism was more frequently found in the group of MPN patients with arterial thrombosis compared to MPN patients who were thrombosis-free [26.5 vs. 11.5%; p = 0.049; odds ratio (OR) 2.68; 95% confidence interval (95% CI) 1.01-7.38]. The CT genotype of the β-fibrinogen c.-148C>T polymorphism occurred more frequently in MPN patients with arterial, and total thrombosis compared to the wild or homozygous genotype (57.7 vs. 40.0 vs. 12.5%; p = 0.027), respectively. The carrier state for the c.-323P10 variant of FVII SNP (summation of P10/10 and P0/10) was more frequent in MPN patients with thrombosis compared to the wild-type genotype carriers (71.4 vs. 43.4%; p = 0.049; OR 3.26; 95% CI 1.01-11.31). The coexistence of heterozygous β-fibrinogen c.-148C>T and FVII c.-323P0/10 SNP, increased the risk of arterial thrombosis (21.1 vs. 3.7%; p = 0.008; OR 6.93; 95% CI 1.38-34.80). The TT genotype of GPla/IIa c.807C>T, the CT genotype of β-fibrinogen c.-148C>T and FVII c.-323P0/10 SNP could be associated with risk of thrombosis in MPN patients.

Keywords: Genetic polymorphism; Myeloproliferative neoplasia; Thrombosis.

INTRODUCTION

The group of Philadelphia-negative (non BCR-ABL) myeloproliferative neoplasms (MPNs), polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF), are known for their different phenotypes but similar complications. The most important of these are vascular events. The incidence of thrombotic complications varies between disease types. They occur in 7.2-15.0% patients with PMF, in 19.0-32.0% patients with ET, and in 30.0-41.0% patients with PV [1-6]. The recent series from Enblom et al. [7], showed that 66.0% of these occurred prior to diagnosis. Janus kinase 2 (JAK2) (p.V617F) and the recently discovered Calreticulin (CALR) mutation are important in the genesis of thrombosis, as the former increases, and the latter decreases the risk of thrombosis [8-11]. Blood cells, interaction between them, and the activation of coagulation factors also play a role in the pathogenesis of thrombosis in non BCR-ABL MPNs. This also includes platelets, as they are important in clot formation and thrombosis. Platelet membrane glycoproteins (GPs) are essential in platelet adhesion and aggregation [12,13]. The main role in the above-mentioned processes is played by GP Ib/IX-V that binds to the von Willebrand factor (vWF) after endothelial cells are damaged [14]. After this process, platelets become activated and promote conformational changes of GP IIb/IIIa that further facilitates the binding of fibrinogen and vWF to the subendothelial layer.
Polymorphisms and Thrombosis in Patients with Non-BCR-ABL MPNs. The PIA1/2 allele of GP IIb/IIa, and its relation to arterial thrombosis in patients with PV have been described in previous studies [16]. The tissue factor and coagulation factor VIIa (FVII) complex is another initiator of the coagulation cascade, which contacts with platelets, resulting in the generation of thrombin on platelet surfaces [17]. The influence of FVII single nucleotide polymorphisms (SNPs) on arterial thrombosis in ET patients has recently been described [18].

The main purpose of our study was to evaluate the effects of different SNPs: platelet GP (c.807C>T of GP Ia/IIa, c.-5T>C of GP Ibα Kozak, GP Ibα variable numbers of tandem repeats (VNTR), GP Ibα c.5792C>T, GP IIb/IIIa PIA 1/2 allele, c.13254T>C of GP VI), vWF c.24/1282A>G, FVII c.-323P0/10, and β-fibrinogen c.-148C>T on the risk of thrombosis in patients with PV, ET, and PMF at the Institute of Oncology of the Lithuanian University of Health Sciences, Kaunas, Lithuania.

Materials and Methods

Patients. This retrospective study included 108 patients. The diagnosis of ET, PV, and PMF was established between 2000 and 2014 at the Department of Hematology of the Institute of Oncology, the Lithuanian University of Health Sciences, Kaunas, Lithuania. Patients who were diagnosed before 2008 were reviewed according to the WHO diagnostic criteria. From a total of 108 patients, 60 (55.6%) patients had ET, 41 (38.0%) patients had PV, and seven (6.5%) were PMF patients. Detailed medical information was collected including the date of diagnosis, the patient’s age, sex, body mass index (BMI), cardiovascular risk factors (smoking, diabetes mellitus, arterial hypertension, and ischemic heart disease), splenomegaly and findings of hematological analyses. We gathered the data on white blood cell (WBC) counts, monocyte, basophile, and platelet counts, medium platelet volume, hemoglobin (Hb), erythrocyte count, hematocrit or packed cell volume (PCV), mean corpuscular volume (MCV), mean corpuscular Hb (MCH) at the time of the diagnosis, as well as JAK-2 p.V617F that was performed from 2009. For JAK-2 p.V617F negative patients, CALR mutation status was performed in 2015. History of previous thrombosis was collected as well. Arterial or venous thrombosis, such as ischemic stroke, myocardial infarction, transient ischemic attack, unstable angina, deep vein thrombosis (DVT) of the legs, thrombosis of abdominal veins, and thrombosis of the pulmonary artery, were defined as vascular events. All comparisons were performed between the thrombosis and the thrombosis-free groups for all ET, PV and PMF patients. This study was conducted with the permission of the regional biomedical research ethics committee and in accordance with good clinical and laboratory practices and the principles of the Declaration of Helsinki. A signed consent form was obtained from all participants.

Genotyping. Venous blood samples were drawn in vacutainers containing EDTA as anticoagulant. Genomic DNA was isolated from peripheral blood leukocytes, using the commercially available DNA extraction kit, according to the manufacturer’s recommendations (Thermo Fisher Scientific Baltics, Vilnius, Lithuania). Primer sequences for genotyping for the detection of the c.807C>T polymorphism of GP Ia/IIa, c.-5T>C polymorphism of GP Ibα, GP IIb/IIIa PIA Kozak, GP IIb/IIIa polymorphism VNTR, GP Ibα c.5792C>T (HPA-2), PIA1/2 polymorphism in GP IIb/IIIa, the von Willebrand factor (vWF) c.24/1282A>G, the FVII c.-323P0/10 polymorphism, β-fibrinogen c.-148C>T polymorphism, c.13254T>C polymorphism of GP VI in Table 1.

Statistical Analyses. The Statistical Package for the Social Sciences (IBM SPSS Statistics) version 22 was used for the association analyses. Categorical variables were described by mean and standard deviation (SD) or median and the sample width (minimum-maximum). The χ2 test was used for categorical variables. Student’s t-test or Mann-Whitney U test was used for the analysis of quantitative variables. The logistic regression analysis distinguished thrombotic risk factors significantly affecting the possibility of thrombosis in the study group. The differences were considered to be statistically significant if the calculated p value was less than the chosen significance level a = 0.05 (p value <0.05).

Results

In total, 108 patients were analyzed. The main clinical characteristics of patients with non-BCR-ABL MPNs in our population are depicted in Table 2. Patients with thrombosis were older [mean age 66.98 years (SD = 13.42) vs. 60.17 years (SD = 15.58) p = 0.016], and had a lower median value of MCV and MCH at the time of diagnosis [83.00 (range 70-100) vs. 87.00 (range 65-101), p = 0.021, 60.17 (range 23-33), p = 0.048, respectively]. In the non-BCR-ABL MPN thrombosis group, patients were predominantly female (54.8 vs. 45.7%), and more patients were positive for the JAK2 p.V617F mutation (52.6 vs. 47.4%, p = 0.002). Concerning

patients with ET and PMF, 11.1% of them were CALR-positive in the thrombosis group compared to 88.9% of the thrombosis-free patients ($p = 0.033$). Other clinical characteristics were similar.

Arterial thrombosis was more frequent in the ET/PMF group than in the PV group (73.5 vs. 26.5%, $p = 0.03$) (Table 3). Forty-five (42.6%) patients had experienced an arterial thrombotic event, 10 (9.3%) patients had experienced a venous event, and four (3.7%) patients had both arterial and venous thrombosis.

Genotype distributions and allele frequencies of the studied polymorphisms in patients with thrombotic complications according to the type of thrombosis are summarized in Table 4. Our data showed a higher prevalence of GP Ia/IIa c.807C>T polymorphism of the TT genotype than the CC wild-type or the heterozygous CT genotype in MPN patients with arterial thrombosis (65.0 vs. 38.2 vs. 42.6%, $p = 0.09$), respectively. The analysis of the c.807 C>T polymorphism TT genotype separately showed that it was significantly more frequent in the MPN patient group with arterial thrombosis compared to the MPN group of thrombosis-free patients [26.5 vs. 11.5%, $p = 0.049$; odds ratio (OR) 2.68; 95% confidence interval (95% CI) 1.01-7.38]. The CT genotype of the β-fibrinogen (c.-148C>T polymorphism) in MPN patients with arterial and venous and venous thrombosis occurred significantly more frequently compared to the CC wild-type or the homozygous TT genotype (57.7 vs. 40.0 vs. 12.5%, $p = 0.027$) and (64.7 vs. 44.4 vs. 25.0%, $p = 0.032$), respectively. The carrier state for the c.-323P10 variant of FVII SNP (summation of P10/10 and P0/10) was significantly more frequent in MPN patients with arterial and venous thrombosis compared to wild-type genotype carriers (71.4 vs. 43.4%, $p = 0.049$; OR 3.26; 95% CI 1.01-11.31). It maintained a borderline significance when analyzed in the arterial thrombosis subgroup only (69.2 vs. 38.2%, $p = 0.06$).

creased the risk of arterial thrombosis in MNP patients (21.1 vs. 3.7%, \( p = 0.008; \ OR 6.93; \ 95\% \ CI 1.38 – 34.80 \)). In the univariate analysis, no statistically significant association was found between the remainder of the tested polymorphisms and thrombosis.

In the multivariate analysis performed on arterial thrombosis considering TT genotype of c.807C>T GP Ia/IIa, CT genotype of β-fibrinogen c.-148C>T, a carrier state for c.-323P10 variant of FVII (summation of P10/10 and P0/10) SNPs, MCV, and age, two of three SNPs (TT genotype of c.807C>T GP Ia/IIa and CT genotype of β-fibrinogen c.-148C>T) as well as MCV and age, retained statistical significance (Table 5). A test of the full model against a constant only model was statistically significant, indicating that the predictors as a set reliably distinguished between MPN patients with arterial thrombosis and those without thrombosis (\( \chi^2 = 21.82, \ p < 0.001 \) with df = 4). Nagelkerke’s \( R^2 \) was 0.33. The overall prediction success was 72.4% (62.2% for thrombosis and 80.0% for no thrombosis).

**Table 5. Multivariate logistic regression.**

| Variable                      | OR  | \( p \) Value | 95% CI-OR |

OR: odds ratio; 95% CI: 95% confidence interval; MCV: mean corpuscular volume.

Separate analyses of different arterial thrombotic events showed more frequent CT genotype of β-fibrinogen c.-148C>T SNP in MPN patients with ischemic stroke compared to other arterial vascular events; however, the results were of borderline significance (75.0 vs. 50.0%, \( p = 0.06 \)). The c.-323P0/10 plus c.-323P10/10 genotype of FVII SNP was statistically significantly more frequent in the ischemic stroke group compared to the thrombosis-free group (33.3 vs. 12.2%, \( p = 0.04 \)).

**DISCUSSION**

The main objective of this study was to evaluate whether SNPs located in genes of platelet glycoprotein Ia/IIa (c.807C>T), glycoprotein Ibb (VNTR; c.5T>C Kozak; c.5792 C>T), glycoprotein IIb/IIIa (PIA1/2), glycoprotein VI (c.13254T>C), vWF (c.24/1282A>G), coagulation FVII (c.-323P0/10), and β-fibrinogen chain (c.-148C>T) could be associated with risk of thrombosis in patients with non BCR-ABL MPNs. The analysis of nine different SNPs provided evidence that the TT genotype (c.807C>T) of GP Ia/IIa, CT genotype (c.-148C>T) of β-fibrinogen chain and coagulation FVII (c.-323P0/10) SNP represent an additional risk factor for thrombosis in patients with non BCR-ABL MPNs.

The c.807C>T SNP of GP Ia/IIa was also studied by Afshar-Kharghan et al. [16] in ET and PV patients. The investigators did not identify any associations between this SNP and thrombotic complications in a cohort of 86 ET and PV patients [16]. The homozygous state (TT genotype) of the above-mentioned polymorphism was identified as an additional risk factor for arterial thrombosis in patients with the antiphospholipid syndrome in the studies of Jimenez et al. [23] and Yonal et al. [24]. Our results suggest that the homozygous state of c.807C>T GP Ia/IIa SNP may increase the risk of arterial thrombosis in non BCR-ABL MPNs. A meta-analysis of 66,155 cases that was published by scientists from China did not show any significant relation between GP Ia/IIa c.807C>T polymorphism and coronary artery disease [25]. In addition, German scientists revealed a modulatory effect of the aforementioned polymorphism on thrombosis development, which can be region- and race-dependent [26].

The impact of coagulation FVII c.-323P0/10 SNP has been recently reviewed by Buxhofer-Ausch et al. [18]. The investigators screened 105 patients with ET meeting the 2008 WHO criteria and 62 patients with early PMF. The c.-323P10 variant of the coagulation FVII showed a statistically significant association with total and arterial thrombosis in univariate as well as in multivariate analysis for patients with ET, but not for those with early PMF [18]. However, the investigators considered that solid data are lacking to explain the mechanism of the relation of c.-323P0/P10 FVII polymorphism with thrombosis. The authors admit the importance of further experiments to evaluate the influence of the aforementioned SNP on the risk of thrombosis [18]. Our cohort of patients was smaller, but it also included a similar number of patients with ET. We also extended the non BCR-ABL MPN cohort to the whole WHO-confirmed non BCR-ABL MPN population. The majority of cases of the heterozygous variant of c.-323P0/P10 FVII SNP were found in the ET cohort,
POLYMORPHISMS AND THROMBOSIS compared to the PV cohort, which is in agreement with data published by Buxhofer-Ausch et al. [18]. We also observed a higher prevalence of this polymorphism in non BCR-ABL MPN patients with arterial and total thrombosis. However, the majority of cases of the c.-323P0/10 FVII SNP retained borderline significance on the multivariate analysis of our non BCR-ABL MPN patient cohort. Our study revealed that the coexistence of both heterozygous genotypes in c.-323P0/P10 FVII and β-fibrinogen c.-148C>T SNP was related to arterial thrombosis in non BCR-ABL MPN patients with the OR of 6.93 and the relative risk of 2.19 for those who were double heterozygous in this study. To the best of our knowledge, a common effect of those two SNPs in non BCR-ABL MPN patients has never been analyzed before. Although the exact pathophysiological mechanism is unclear, we can only speculate that the simultaneous occurrence of two or more prothrombotic SNPs can activate the hemostatic cascade that further predisposes the development of thrombosis in non BCR-ABL MPNs.

Our results showed a tendency of a higher frequency of the β-fibrinogen CT genotype (c.-148C>T SNP) in patients with total and arterial thrombosis than in non BCR-ABL MPN patients who did not experience vascular events. The effect of this SNP was evaluated in a large population of Chinese patients with ischemic stroke and cerebral infarction, but not in non BCR-ABL MPNs [27,28]. There was also evidence that β-fibrinogen c.-148C>T SNP is functional and associated with elevated plasma fibrinogen levels [29]. The carriers of the heterozygous genotype of this SNP showed a trend toward a higher risk of ischemic stroke in our cohort, although, considering the small number of patients, it was of borderline significance. This gave rise to a hypothesis that different single nucleotide polymorphisms could be potential confounders in vascular-specific events.

The age of non BCR-ABL MPN patients who experienced thrombotic events is already a well-known risk factor for thrombosis [2,30]. Our results also confirmed older age as a risk factor for thrombosis. We observed lower MCV and MCH indices in the thrombosis group compared to the thrombosis-free group. However, this difference could be due to the fact that three distinct non BCR-ABL MPN subtypes were studied in this cohort. Differently from Carobbio et al. [30], we were not able to reveal any cardiovascular risk factor as a predictor for thrombosis, probably due to the lower prevalence of cardiovascular risk factors in our cohort. The JAK2 p.V617F mutation is considered to be a risk factor for thrombosis in non BCR-ABL MPN patients. This was observed in many studies. JAK2 p.V617F mutation is also included in the International Prognostic Score of thrombosis in WHO-essential thrombocythemia (IPSET-thrombosis) model for ET patients [31]. The results of our study also confirmed that this mutation was a risk factor for thrombosis in non BCR-ABL MPN patients. Conversely, Calreticulin mutation was associated with a decreased risk of thrombosis in ET and PMF patients in our cohort.

Polymorphisms of the factor V Leiden (FVL) and the prothrombin gene G20210A were recognized as risk factors for venous thrombosis from 1994 [32]. They were also investigated in the thrombotic approach of myeloproliferative neoplasms. Ruggeri et al. [33] retrospectively investigated FVL in a cohort of 304 ET and PV patients. The study results revealed that the prevalence of FVL mutation in PV and ET patients was similar to that observed in the normal population. Moreover, the FVL mutation was not associated with arterial or venous thrombosis. However, the authors stated that the FVL mutation is associated with the risk of venous thrombosis recurrences [33]. Schwarz et al. [34] recognized the FVL mutation to be a significant additional risk factor in the occurrence of venous thrombosis in a prospective analysis of 1179 ET patients. De Stefano et al. [35] investigated MPN patients younger than 60 years of age. The study revealed that the risk of thrombosis was increased when FVL and prothrombin gene G20210A mutation coexist with the JAK2 p.V617F mutation in ET patients [35]. Similar results were demonstrated by Tevet et al. [32] in 192 patients with MPN. According to them, the thrombotic risk was higher in the JAK2 p.V617F mutation subgroup and it was further increased by the presence of the FVL mutation [36].

Unfortunately, we did not analyze the aforementioned mutations. However it would be interesting to investigate these thrombophilic factors in conjunction with our studied platelet receptor polymorphisms. Moreover, our study had a few limitations, such as small group size, the absence of controls, and non BCR-ABL MPN heterogeneity, as three types of the disease were analyzed. We also did not measure FVII or plasma fibrinogen levels in our patients.

In conclusion, this study was focused on polymorphisms that were located in genes coding different players of the primary and secondary hemostatic system, which reflects several pathophysiological paths from platelet plug to fibrin formation. This study analyzed a large number of SNPs in non BCR-ABL MPN patients, bringing up-to-date evidence of what platelet and coagulation factors can contribute to thrombotic complications. The coexistence of several different polymorphisms as well as vascular-specific event polymorphisms could be a clue for further investigations in order to delineate the pathophysiology of thrombosis in non BCR-ABL MPN patients.
AKNOWLEDGMENTS

This study was supported by grants from the Lithuanian University of Health Sciences Research Fund (Kaunas, Lithuania) and by a research grant from Novartis Pharma (Vilnius, Lithuania). Authors’ contributions: RD conceived the study, participated in its design, collected clinical data, analyzed the data, performed statistical analyses, and drafted the manuscript. MR conceived the study and analyzed the data. RU, AS, RJ, RG conceived the study, participated in its design and coordination, interpreted the data, carried out molecular genetic testing, collected clinical data, and helped to draft the manuscript. RG and EJ conceived the study, participated in its design and coordination, collected clinical data, and helped to draft the manuscript. RS participated in data interpretation and performed statistical analyses. All authors read and approved the final manuscript.

Declaration of Interest. The authors report no conflicts of interest. The authors alone are responsible for the content and writing of this article.
