Comparative Study of Antioxidant Activity of Some Amides

Abstract

The aim of this study was to evaluate the antioxidant activities of five amides: benzanilide 1, dodecanilide 2, N-cyclohexyloctamide 3, acetanilide 4, and acetonphenophen (paracetamol) 5, and to compare them to those of standard antioxidants, i.e. butylated hydroxyanisole (BHA), butylated hydroxy toluene (BHT), ascorbic acid (vitamin C) and α-tocopherol (vitamin E). Three common experimental tests were used to assess their antioxidant properties: 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity, ferric ions reducing antioxidant power (FRAP) and β-carotene/linoleic acid assays. The amides 1-3 proved to be antioxidant as per three methods; the fatty anilide 2 showed the highest radical scavenging activity, whereas the fatty amide 3 showed the lowest one. Increasing the concentration resulted in an increased ferric ions reducing antioxidant power for all examined amides; the reducing power of fatty anilide 2 was relatively higher than those of benzanilide 1 and fatty amide 3. Oxidation of the linoleic acid was strongly inhibited by all amides. The obtained results were comparable to antioxidant properties of the standard antioxidants.

Keywords: Amide derivatives; Antioxidant activity; β-Carotene bleaching; DPPH assay; nFRAP assay

Abbreviations: BHA: Butylated Hydroxyanisole; BHT: Butylated Hydroxy Toluene; Vitamin C: Ascorbic Acid; Vitamin E: Tocopherol; DPPH: Diphenyl-1-Picrylhydrazyl; FRAP: Ferric Ions Reducing Antioxidant Power; AD: Alzheimer’s Disease; PD: Parkinson’s Disease; ALS: Amyotrophic Lateral Sclerosis

Introduction

To recall, lipids containing carbon-carbon double bond(s) are vulnerable to oxidation under aerobic conditions and are easily attacked by free radicals, giving rise to harmful products; such deteriorating phenomenon is called ‘lipid oxidation’. Antioxidants are organic molecules which can scavenge free radicals and thus avoid or delay the progress of this lipid oxidation. For this matter, they generally exist as additives in food products. They are promising agents for management of oxidative stress related diseases such as cancer, arthritis, aging, autoimmune disorders, Alzheimer’s disease (AD), Parkinson’s disease (PD) and amyotrophic lateral sclerosis (ALS) [1]. Therefore, there is a growing interest in substances that exhibit antioxidant properties, which are supplied to humans and animals as food components or as specific pharmaceuticals. Several methods have been developed to evaluate antioxidant activities of natural and synthetic substances [2,3].

Amide derivatives play an important role in biological activities [4-7]. For example, the uses of the class of anilides in medicine, pharmacy, biology and other related fields are well-known and are as such because of their biological activities including anti-bacterial, anti-fungalicidal, anti-convulsant, anesthetic, and platelet aggregation [10]. Various anilides have also found a wide applicability as bioactive species (antimicrobial, antioxidant and antatherosclerotic agents) [11,12]. Moreover, they are also involved as intermediate products in the synthesis of therapeutic agents [8,9].

In the present work, the antioxidant activities of three synthesized amides: benzanilide 1, dodecanilide 2, N-cyclohexyloctamide 3, and of two known ones: acetanilide 4 and acetonphenophen (paracetamol) 5, were evaluated and compared to those of standard antioxidants such as butylated hydroxyanisole (BHA), butylated hydroxy toluene (BHT), ascorbic acid (vitamin C) and α-tocopherol (vitamin E). The antioxidant activities were estimated with three different methods: 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity, ferric ions reducing antioxidant power (FRAP) and β-carotene/linoleic acid assays.

Materials and Methods

Chemicals

Chemicals were of analytical grade and were purchased from one of the following chemical companies: Sigma-Aldrich, Merck, Prolabo, and Biochem.

Synthesis

The three synthesized amides (1-3) were prepared from aniline and carboxylic acids by the reported procedures [13,14]. The chemical structures of the tested amides are illustrated in Figure 1.

General synthetic procedure for 1, 2, and 3: Benzanilide 1 was first prepared via a solvent-free reaction by the conventional method as described earlier by [14] as follows. A mixture of aniline and benzoic acid was heated at a temperature range of
160-200 °C for a time period of 3-4h. The water from the reaction was continuously distilled off (Eq.1).

Under identical operating conditions, dodecanilide 2 was prepared by reaction of an excess of aniline with dodecanoic acid (Eq.1) [15], and N-cyclohexyloctanamide 3 was obtained by reaction of an excess of cyclohexylamine with octanoic acid. The produced white solids were recrystallized in ethanol to afford colorless needle-like crystals. The different amides 1-3 were obtained as white crystals in yields as high as 73-92%.

$$R' = \text{C}_6\text{H}_{11}, R'' = \text{C}_6\text{H}_{5}, R = \text{C}_7\text{H}_{15}, R' = \text{C}_6\text{H}_{11}, R = \text{C}_8\text{H}_{17}, R' = \text{C}_6\text{H}_{5}, 160-200^\circ \text{C} \text{ for 3-4h. The water from the reaction was continuously distilled off (Eq.1).}$$

$$\text{DPPH radical scavenging activity}(\%) = \left(\frac{A_\text{control} - A_\text{sample}}{A_\text{control}}\right) \times 100$$

Where $A_\text{control}$ is the absorbance of the control reaction (DPPH solution without the compound to be tested) and $A_\text{sample}$ the absorbance of sample. The concentration of anilides providing 50% inhibition (IC$_{50}$) was calculated from the graph of the plot of inhibition extent (in %) against amide concentration (in $\mu$g/mL) [20,21].

**Reducing power assay:** The reducing power of a substance is a measure of its reductive ability as antioxidant, and it is estimated by the transformation of ferric ion $\text{Fe}^{3+}$ to ferrous one $\text{Fe}^{2+}$ in the presence of the sample extract [21]. The ability to reduce $\text{Fe}^{3+}$ can be attributed to the hydrogen donation capacity from phenolic compounds as described by Shimada et al. [22]. In this assay, the yellow color of the test solution turns green or blue according to the reducing power of the test sample. The capacity of the antioxidant to reduce the ferric ferricyanide complex to the ferrous one was determined based on absorbance at 700nm after incubation; the more intense the absorption, the greater the reducing power [23,24].

The ferric reducing potential of anilides was assayed as described by Oyaisu [25]. Different concentrations of amides 1-5 in 1mL of ethanol were mixed with 2.5mL of phosphate buffer (0.2M, pH 6.6) and 2.5mL of potassium ferricyanide [K$_3$Fe(CN)$_6$] (1%), then the mixture was incubated at 50°C for 20min. Afterwards, 2.5mL of trichloroacetic acid (10%) was added to the mixture, which was then centrifuged at 1000rpm for 10min. Finally, 2.5mL of the upper layer solution was mixed with 2.5mL of distilled water and 0.5mL of FeCl$_3$ (0.1%), and the absorbance was measured at $\lambda_{\text{max}} = 700nm$.

**β-Carotene bleaching assay**

β-Carotene bleaching method is based on β-carotene oxidation (discoloring) induced by the products from linoleic acid oxidative degradation. The presence of an antioxidant prevents the reducing action of β-carotene which remains yellowish-orange in color [26].

β-Carotene bleaching assay was conducted by using the method suggested by Tepe [27] with some modifications. A solution of β-carotene was prepared by dissolving 0.5mg of β-carotene in 1 mL of chloroform. 25µl of linoleic acid and 200mg of Tween 80 were added. Chloroform was completely evaporated using a vacuum evaporator. Then, 100mL of distilled water saturated with oxygen were added with a vigorous shaking. 2.5mL of this reaction mixture were dispersed in test tubes and 350µL portions of the samples prepared at 2mg/mL concentrations were added; the ensued emulsion system was incubated up to 48 hours at room temperature. The same procedure was repeated for positive control BHT and a blank. The absorbances of the mixtures were measured at $\lambda_{\text{max}}=490nm$ at regular time intervals. The relative antioxidant activity (AA) was calculated according to the following equation:

$$AA(\%) = \left(\frac{A_{\text{control}(\text{48h})} - A_{\text{sample}(\text{48h})}}{A_{\text{control}(\text{48h})}}\right) \times 100$$

Where $A_{\text{sample}(\text{48h})}$ is the absorbance of the sample after 48h and $A_{\text{control}(\text{48h})}$ the absorbance of BHT used as a positive control.
Results and Discussion

Synthesis

The derivative anilides synthesized were obtained in quantitative yields. Their structures were confirmed by spectroscopic analyses, including UV-visible, IR, 1H-NMR and MS, as reported earlier [13].

Antioxidant activity

**DPPH radical scavenging activity:** DPPH is a common reagent used to quantify the free radical scavenging activity of antioxidants. By virtue of being a stable free radical, the delocalization of the free electron gives rise to a deep violet color, characterized by an absorption band in ethanol solution at about 517nm.

In the DPPH radical-scavenging assay, an antioxidant reacts with DPPH, leading to the reduced form of the latter; DPPH pulls out either an electron or hydrogen atom from the antioxidant. As a result, the color changes from violet to yellow. The color fading extent proves indirectly the radical-scavenging capacity of the antioxidant [19].

DPPH has been used extensively as a free radical to evaluate reducing substances [28] and is a useful reagent for investigating the free radical scavenging activities of compounds [29]. In its radical form, DPPH absorbs at 517nm, but upon reduction with an antioxidant, its absorption decreases due to the formation of its non-radical form, DPPH–H [4]. Thus, the radical scavenging activity in the presence of a hydrogen donating antioxidant can be monitored as a decrease in absorbance of DPPH solution [3]. The results of percentage inhibition of the DPPH radical by standard antioxidants and the different amides are represented in Figure 2.

As can be seen, the amides present a scavenging capacity of free radicals. It is also noted that the efficiency of the antioxidant increased with the concentration of the tested amides. The IC$_{50}$ values, which are concentrations of antioxidants required to reduce 50% the DPPH concentration, are illustrated in Figure 3.

**Reducing power assay**

The reducing power of a compound is related to its transfer capacity of electrons and can serve as a significant indicator of its potential antioxidant activity [21]. The reducing powers of standard antioxidants and of synthesized anilides at 700nm (C=100μg/mL) are presented in Figure 4.

As can be seen in Figure 4, the amides 1-5 demonstrated powerful Fe$^{3+}$ reducing ability. By comparing the obtained results, we note that the anilide 5 (paracetamol) is the most active, whereas a weaker reducing power was observed for the amide 3. It can be noticed that the reducing powers of these compounds were close to that of vitamin E but were lower than that of the remaining reference antioxidants (BHT, BHA and vitamin C).

**β-Carotene bleaching assay**

The β-carotene/linoleic acid test determines the inhibition rate of the oxidation of linoleic acid to confirm anti-lipoperoxidation effects of sample. The β-carotene bleaching method is widely used to measure the antioxidant activity of plant extracts. This method was the least active. Based on the IC$_{50}$ values, the antioxidant capacity of the tested amides was lower than that of the control molecules. The DPPH scavenging potential of anilides may be due to their reducing action by donating hydrogen atom to a free radical, reducing it to nonreactive species [30].
is based on the fact that linoleic acid produces a free radical which is reduced by β-carotene. The addition of an antioxidant allows a delay of the discoloration kinetics of β-carotene [26]. According to several authors, the test of inhibition of the oxidation of linoleic acid coupled with β-carotene, appeared very useful as a model of lipid peroxidation in biological membranes [32].

The bleaching kinetics of β-carotene in the presence of the synthesized amides and reference antioxidants (BHT) are shown in Figure 5. As seen in Figure 5, all amides inhibited the oxidation of β-carotene. This effect is due to either the inhibition of linoleic acid peroxidation or the radical scavenging of hydroperoxides formed during the peroxidation of linoleic acid (scavenger effect). The antioxidant activity (RAA) of anilides relative to that of the BHT in β-carotene/linoleic acid system is shown in Figure 6. The results in Figure 6 would suggest that all the amides inhibited efficiently the oxidation of linoleic acid/β-carotene system when compared to the negative control. These values were very similar to that of the antioxidant BHT.

**Figure 5:** Antioxidative potentials of amids (1-5) and positive control BHT in β-carotene/linoleic acid system.

**Figure 6:** Relative antioxidant activity (RAA) of various amides and positive control BHT in β-carotene/linoleic acid system.

### Conclusion

In this work, we evaluated the antioxidant activity of five amides through three methods: 2, 2-diphenyl-1-picryl-hydrazil (DPPH) free radical scavenging, Ferric reducing antioxidant power (FRAP), and bleaching of β-carotene. The results showed that the amides exhibit considerable antioxidant activities compared to those of the reference antioxidants. The antioxidant efficacy increases with the concentration of anilides and is directly related to the nature of the substituents on the amide group. These activities were more significant for fatty N-aromatic amide, and the one with hydroxyl group (paracetamol) showed the highest antioxidant activity. These in vitro assays indicate that amide derivatives can be utilized as antioxidants in pharmaceutical applications and others such as food supplements.
