(Dated: November 30, 2020)

We study the quantum backflow problem in the noncommutative plane. In particular, we have considered a charged particle with and without an oscillator interaction with noncommuting momentum operators and examined angular momentum backflow in each case and how they differ from each other. We also propose a probability associated with the occurrence of angular momentum backflow and investigate whether or not the probability depends on a physical parameter, namely the magnetic field.

I. INTRODUCTION

Quantum backflow is a striking but still relatively not well known quantum effect for which, given a state containing only positive momentum components, the probability of observing the particle to the right of a given reference point ($x = 0$ for instance), may actually decrease over time. This amounts to saying that there is a flow of the probability density in the direction opposite to that of the momentum. In other words, it means that a right-moving particle can actually move to the left. The effect was first discovered by Allcock in his works on arrival time and it was noted that the probability current could be negative for states consisting only of positive momenta [1–3].

A detailed investigation of the problem was carried out and an upper bound to the amount of probability that can flow in a direction opposite to momentum was found [4]. This limit $c_{bm}$ has a numerically computed value of about 0.04 and the most surprising fact is that it is a dimensionless value, independent of any physical parameter. Because of that it has been considered as “a new quantum number”. This may cause some problems in the naive classical limit $\hbar \to 0$ as it has been observed how there are different systems for which the maximum amount of backflow becomes dependent on some physical parameters. However it has been shown [5], in a one dimensional setting, that with a more realistic approach introducing quasi-projectors $\theta(x)$ [6] of the position operator smoothed, over a length scale $\sigma$, instead of the ideal projector $\theta(x)$, the limit $\hbar \to 0$ reproduces correctly the classical behavior, i.e. no backflow. On the other hand, in the case of a Dirac particle backflow was found to depend on some physical parameters [7, 8] but not in a way that explains the classical limit. See also [9, 10] for a discussion of the quantum backflow in the Dirac equation of spin 1/2 free particles.

There have been attempts to improve the value $c_{bm}$ [11, 12]. In particular, in ref [12] an operator associated with the backflow problem was found and was used to improve upon the value of $c_{bm}$. However, although the problem of finding the exact eigenstate corresponding to the upper bound of $c_{bm}$ (maximum backflow) has still not been solved analytically, there are plenty of constructions of backflowing states.

In an interesting approach [13], the backflow problem was studied using non normalizable wave functions and it was found that in relation to the superoscillations a constraint regarding spatial extension exists. By measuring the fraction of the $x$-axis subject to backflow, the probability of finding the particle in one one of these regions, and their temporal evolution was found. Interestingly quantum backflow has also been studied in different contexts like decay of metastable states [14], in multiparticle systems [15], appearance of classically forbidden probability flux [16] etc. In another recent work [17] the author discusses the relationship between quantum backflow and quantum reentry (QR), the effect in which a wave packet evolving from a localized spatial region partially returns to this region in the absence of external forces, providing a unifying treatment of the two effects.

It may be noted that in interacting systems, the backflow problem can be studied in different ways. For example, quantum backflow has been studied in the context of scattering states in ref. [18] where it has been shown that those features of the probability operator in the quantum backflow in the case of no interactions are also found when interactions are present. The most important properties of the quantum backflow are stable against the introduction of interaction potentials even strong ones.

In another example [19, 20], considering an electron in a magnetic field, the backflow problem has been formulated in terms of an effective angular momentum defined for states given as a superposition of eigenstates and written out the in phase-amplitude form. It was shown [19] that in certain regions of space the effective angular momentum can be directed in a direction opposite to that of the wave function’s components. These results are very interesting since they show that while the usual momen-
tum quantum backflow is related to the uncertainty relation between the position coordinate and the momentum [19], the angular momentum backflow relates to the uncertainty relations between the polar (azimuthal) coordinate and the $L_{\text{can}}$ component of the angular momentum operator. This could mean that similar effects could be found for other models where additional interactions are present.

During the past decade or so studies on quantum gravity and string theory indicate that space may be noncommutative in nature [21–29]. In order to test the effect of space noncommutativity several quantum mechanical models e.g., harmonic oscillator [24, 25], central field problems [26, 27], hydrogen problem [28, 29] etc., have been studied within the framework of noncommutative quantum mechanics. In all these cases attempts were made to determine the effect of noncommutativity by finding the dependence of some observable like energy on the parameter(s) of noncommutativity. In some other cases the effect of noncommutativity on phenomena like chirality phase transition [30], Hall effect in Dirac matter like graphene [31–33] etc., have been studied. However, in view of the fact that no conclusive evidence regarding noncommutative nature of space or momenta has yet been conclusively established, it is of interest to find new models where this effect may eventually be detected. In this context it may be noted that in recent years experiments have been proposed to detect quantum backflow in Bose-Einstein condensate [34] as well as in the field of optics [35].

In the present paper our objective is to study quantum backflow problem on the the noncommutative plane. To be more specific, we shall consider two models: (1) The first one is a noncommutative analogue of a charged particle in the presence of a homogeneous magnetic field, (2) A noncommutative oscillator in a homogeneous magnetic field. In both the models we shall study angular momentum backflow [19] and examine to what extent noncommuting nature of the momentum operators affects quantum backflow. In this context it may be noted that the second model is a more general one from which the first one can be obtained by setting the oscillating frequency equal to zero. Nevertheless we have treated them separately as the first one has a commutative analogue [19] with which we may compare our results and the second one is a completely new one. Secondly, it also helps us to find out the difference in backflow pattern when an additional interaction is present. Finally, we shall also make an attempt to quantify angular momentum backflow by defining a suitable probability associated with it. The organization of the paper is as follows: in Section II we formulate the model(s) on the noncommutative plane and obtain the solutions; in Section III we study angular momentum backflow in a noncommutative setting; in Section IV we define a probability associated with angular momentum backflow and discuss some of its features; finally Section V is devoted to a conclusion.

II. NONCOMMUTATIVE CHARGED PARTICLE SUBJECT TO AN OSCILLATOR IN A MAGNETIC FIELD

To begin with we note that the Hamiltonian $H_{\text{NC}}$ for a particle of charge $q$ in the noncommutative plane in the presence of a homogeneous magnetic field subject to an oscillator potential has the same functional form as the one in the commutative plane. Thus the Hamiltonian $H_{\text{NC}}$ is taken to be of the form:

$$H_{\text{NC}} = \frac{1}{2\mu} \left( \hat{p} - \frac{q}{c} \hat{A} \right)^2 + \frac{1}{2} \mu \omega^2 (\hat{x}^2 + \hat{y}^2),$$

where $c$ is the velocity of light, and $\mu$ is the particle’s mass. We choose the vector potential to be analogous to the one in the commutative plane producing a constant magnetic field along the $z$ axis as $B = B\hat{k}$, $\hat{k}$ being the $z$-axis unit vector:

$$\hat{A} = (-B\hat{y}/2, B\hat{z}/2).$$

The commutation relation between the non-commuting coordinates and momenta are given by

$$[\hat{x}, \hat{y}] = i\theta, \quad [\hat{p}_x, \hat{p}_y] = i\eta,$$  

where $\theta, \eta \in \mathbb{R}$.

Then for an electron, charge $q = -e$, the above noncommutative Hamiltonian reads

$$H_{\text{NC}} = \frac{1}{2\mu} \left( \hat{p}_x - \frac{eB}{2c} \hat{y}, \hat{p}_y + \frac{eB}{2c} \hat{x} \right)^2 + \frac{1}{2} \mu \omega^2 (\hat{x}^2 + \hat{y}^2).$$

Using the commutation relations in Eq. (3) we obtain:

$$\left( \hat{p}_x - \frac{eB}{2c} \hat{y} \right)^2 = \hat{p}_x^2 + \left( \frac{eB}{2c} \right)^2 \hat{y}^2 - \frac{eB}{c} \hat{y} \hat{p}_x,$$

$$\left( \hat{p}_y + \frac{eB}{2c} \hat{x} \right)^2 = \hat{p}_y^2 + \left( \frac{eB}{2c} \right)^2 \hat{x}^2 + \frac{eB}{c} \hat{x} \hat{p}_y.$$

It is now necessary to express the non-commuting coordinates and momenta in terms of commuting ones. This can be achieved using the Seiberg-Witten map [37] and the transformations are given by:

$$\hat{x} = x - \frac{\theta}{2\hbar} p_y, \quad \hat{p}_x = p_x + \frac{\eta}{2\hbar} y,$$

$$\hat{y} = y + \frac{\theta}{2\hbar} p_x, \quad \hat{p}_y = p_y - \frac{\eta}{2\hbar} x,$$

where $(x, y)$ and $(p_x, p_y)$ denote commuting coordinates and momenta. Now using the relations in Eq. (7) the Hamiltonian in Eq. (4) can be written as:

$$H = \frac{1}{2\mu} \left[ \left( 1 - \frac{eB\theta}{4\hbar} \right) p_x + \left( \frac{\eta}{2\hbar} \right) \left( \frac{eB}{2c} \right) y \right]^2 + \frac{1}{2\mu} \left[ \left( 1 - \frac{eB\theta}{4\hbar} \right) p_y - \left( \frac{\eta}{2\hbar} \right) \left( \frac{eB}{2c} \right) x \right]^2 + \frac{1}{2} \mu \omega^2 \left[ \left( x - \frac{\theta}{2\hbar} p_y \right)^2 + \left( y + \frac{\theta}{2\hbar} p_x \right)^2 \right].$$
The above expression can be more conveniently written in terms of the following frequencies:

\[
\tilde{\omega} = \frac{eB}{2\mu c}, \quad \omega_y = \frac{2\hbar}{\mu \theta}, \quad \omega_\eta = \frac{\eta}{2\hbar \mu}.
\]  

(9)

Then we find:

\[
H_{\text{NC}} = \alpha \left( \frac{p_x^2 + p_y^2}{2\mu} + \frac{1}{2} \mu \beta (x^2 + y^2) + \gamma (xp_y - yp_x) \right), \quad (10)
\]

where constants $\alpha, \beta, \gamma$ are given by:

\[
\alpha = \left( 1 - \frac{\tilde{\omega}}{\omega_\eta} \right)^2 + \frac{\omega_\eta^2}{\omega_\eta^2}, \quad (11a)
\]

\[
\beta = (\tilde{\omega} - \omega_\eta)^2 + \omega_\eta^2, \quad (11b)
\]

\[
\gamma = (\tilde{\omega} - \omega_\eta) \left( 1 - \frac{\tilde{\omega}}{\omega_\eta} \right) - \frac{\omega_\eta^2}{\omega_\eta}. \quad (11c)
\]

Upon recognizing that the last term in Eq. (10) involves the $z$ component of the angular momentum operator $L_z^{\text{can}} = (r \times p)_z = xp_y - yp_x$, the non-commutative Hamiltonian can be written in the following form:

\[
H_{\text{NC}} = \sqrt{\alpha} \left\{ \frac{p_x^2 + p_y^2}{2\mu} + \frac{1}{2} \mu \beta (x^2 + y^2) + \gamma \sqrt{\alpha} L_z^{\text{can}} \right\},
\]

(12)

and therefore defining

\[
M = \frac{\mu}{\sqrt{\alpha}}, \quad (13a)
\]

\[
\Omega = \sqrt{\beta}, \quad (13b)
\]

we can finally write:

\[
H_{\text{NC}} = \sqrt{\alpha} \left[ H_0^{2D} + \frac{\gamma}{\sqrt{\alpha}} L_z^{\text{can}} \right], \quad (14)
\]

where:

\[
H_0^{2D} = \frac{p_x^2 + p_y^2}{2M} + \frac{1}{2} M \Omega^2 (x^2 + y^2). \quad (15)
\]

We see therefore that the Hamiltonian in Eq. (10) can be related to $H_0^{2D}$, the Hamiltonian of a well known and exactly solvable non-relativistic system—that of a two dimensional isotropic (or circular) harmonic oscillator (of frequency $\Omega$ and mass $M$). The eigenfunctions and eigenvalues of this system are well known [38] and can be readily used to solve the non commutative Hamiltonian of Eq. (14) since the angular momentum operator $L_z^{\text{can}}$ commutes with $H_0^{2D}$. Thus, the complete set of eigenfunctions and the corresponding eigenvalues for the NC Hamiltonian are identified by a radial quantum number $n = 0, 1, 2, \cdots$ and the angular momentum quantum number $m = 0, \pm 1, \pm 2, \cdots$ [38] and are given by:

\[
\psi_{n,m}(r, \varphi) = C_{n,m} r^{|m|} e^{\frac{-r^2}{4a_B^2}} \times
\]

\[
_1 F_1 (-n, |m| + 1; \frac{r^2}{2a_B^2}) e^{im\varphi}, \quad (16a)
\]

\[
\varepsilon_{n,m} = \hbar \Omega (|m| + 1 + 2n) \sqrt{\alpha} + \hbar m \gamma, \quad (16b)
\]

where $a_B = \sqrt{\frac{\hbar}{2M\Omega}}$ and $C_{n,m}$ are normalization constants that can be easily computed as:

\[
C_{n,m} = \frac{\hbar^{-|m|+1}}{\Gamma(|m| + 1) \sqrt{\Gamma(n+1)}} \quad (17)
\]

By setting $\omega = 0$ we obtain the results for the non-commutative charged particle in a magnetic field, which we will discuss as the commutative counterpart has already been studied [19]. At this point we digress a little to point out some features of the spectrum. We note that the spectrum is not degenerate because of the presence of the last term on the r.h.s. of Eq. (16b). However one may easily verify that the usual degeneracy pattern is recovered when $\omega = 0, \theta = 0$. We shall see later that non degeneracy of the spectrum has interesting consequences.

So far we have described the systems keeping both space as well as momentum noncommutativity. It may be noted that momentum noncommutativity ($\eta \neq 0$) produces a magnetic field like effect in the commutative plane while space non-commutativity ($\theta \neq 0$), although it affects other parameters like the mass, does not produce such a magnetic field like effect on the commutative plane. Thus we shall henceforth consider only noncommuting momentum operators. Note that in this case the Hamiltonian can be written in the form:

\[
H = \frac{1}{2\mu}(p - A)^2 + \frac{1}{2} \mu \omega^2 (x^2 + y^2), \quad (18)
\]

where $A = \frac{1}{2}[(B + \frac{eB}{c})y, (B - \frac{eB}{c})x]$. In the case without the oscillator part, a critical value is found for the magnetic field $B_{cr}$ for which the Hamiltonian becomes that of a free particle of mass $M$ given by (13). Imposing the condition $\Omega = 0$ one immediately gets the value of the critical field:

\[
B_{cr} = \frac{\eta c}{\hbar e}. \quad (19)
\]

On the other end it is easily seen that when the oscillator is present ($\omega \neq 0$) then the equation $\Omega = 0$ does not have (real) solutions implying that in this case there is no critical value of the magnetic field.

### III. ANGULAR MOMENTUM BACKFLOW ON THE NONCOMMUTATIVE PLANE

Before studying angular momentum backflow, let us note that the current density for a state described by the wave-function $\Psi$ is given by:

\[
\mathbf{j} = \frac{\hbar}{2M i} [\psi^* \nabla \psi - \psi \nabla \psi^*] - e \mathbf{A} \psi^* \psi - \mathbf{j}_1 - \mathbf{j}_2. \quad (20)
\]
In order to have phase form:

\[ \frac{\partial}{\partial \varphi} \text{Arg} \Psi(r, \varphi) = \text{Im} \frac{\partial \Psi(r, \varphi)}{\partial \varphi} \text{Im} \Psi(r, \varphi) \] (22a)

\[ \left( \frac{\mu r}{\hbar} \right) e_{\varphi} \cdot j_1(r, \varphi) \rho \] (22b)

where \( \Psi(r, \varphi) \) denotes the wavefunction in the amplitude-phase form:

\[ \Psi(r, \varphi) = \sqrt{\rho(r, \varphi)} \exp \left[ i \int_0^\varphi d\varphi' m_{\text{eff}}(r, \varphi') \right] \] (23)

\( e_{\varphi} \cdot j_1(r, \varphi) \) being the probability current along the azimuthal direction and \( \rho = |\Psi(r, \varphi)|^2 \) is the probability density \([38]\).

### A. Model without Oscillator Interaction: \( \omega = 0 \)

Now we consider a specific example of a (normalized) wavefunction which is a simple sum of three eigenfunctions, as given by Eq. (16). We consider only the \( n = 0 \) states with three different, non positive, magnetic quantum numbers \((-2, 1, 0)\). For the sake of comparison this is analogous to what has been done in [19] and allows to compute explicitly the local effective magnetic quantum number \( m_{\text{eff}}(r, \varphi) \) in a simple closed form. Using Eq. (16) we obtain the state \( \Psi_0(r, \varphi) \) as:

\[ \Psi_0(r, \varphi) = \frac{1}{\sqrt{3}} \sum_{m=0}^2 c_m(r) e^{-im\varphi} = \frac{1}{\sqrt{3}} \left[ c_0(r) + c_1(r)e^{-i\varphi} + c_2(r)e^{-2i\varphi} \right], \] (24)

where the coefficients \( c_m(r) \) are given by

\[ c_m(r) = C_{0,m}|m| e^{-\frac{\eta^2}{4a_B^2}}, \] (25)

and we note that \( C_{0,m} = C_{0,-m} = C_{0,|m|} \) as given by Eq. (17). Note that the state in Eq. (24) is a simple sum of three eigenstates from Eq. (16a) with \( n = 0 \) and angular momentum \( L_{\text{anz}} \) is \(-\hbar(0, 1, 2)\) respectively.

It is important to note that, in the model without oscillator interaction an infinite degeneracy for fixed \( n \) and non positive \( m \) is present, therefore, for our wavefunction, time dependence occurs only in the form of an immaterial global phase. Time dependence for the model with oscillator interaction will be discussed in the next sub-section (III B).

From Eq. (22a) we can determine the effective value of the quantum number \( m_{\text{eff}}(r, \varphi) \) for the superposition in Eq. (24):

\[ m_{\text{eff}}(r, \varphi) = -\frac{c_1^2 + 2c_2^2 + c_0 c_1 \cos \varphi + 3c_1 c_2 \cos \varphi + 2c_0 c_2 \cos 2\varphi}{c_0^2 + c_1^2 + c_2^2 + 2c_0 c_1 \cos \varphi + 2c_1 c_2 \cos \varphi + 2c_0 c_2 \cos 2\varphi}. \] (26)

In order to have \( m_{\text{eff}} > 0 \), we need to look for values of \((r, \varphi)\) where \( m_{\text{eff}} \) passes through zero. This leads to

\[ \sqrt{2}r \cos^2 \varphi + \left( \frac{a_B}{\sqrt{2}} + \frac{3r^2}{4a_B} \right) \cos \varphi + \frac{r^3}{4a_B} + \left( \frac{1 - \sqrt{2}}{2} \right) r = 0. \] (27)

In the non-commutative setting the form of Eq. (27) remains the same for both models and the differences lie in the different dependence of frequency and mass contained in \( a_B \) on the parameter \( \eta \). To make an easy comparison with different models, it is convenient to denote the system in dimensionless units by using the parameter \( a_B \) as a unit of length, thus, in general, we will use the value \( a_B \) as in the commutative setting. It is important to note that, as the magnetic field changes, \( a_B \) also changes, which means that the unit of length will change as well. We recall that in some previous works a bound on the parameter \( \eta \) was obtained by comparing non-commutative predictions with measurements and is

\[ \sqrt{\eta} \lesssim 2.26 \frac{\mu eV}{c}. \] (28)

Thus we set \( \eta/m_e^2 c^2 = 10^{-25} \), \( m_e \) being the electron mass and it is consistent with (28). Next, choosing different values of the magnetic field around the critical value, \( B_{\text{cr}} \), given in Eq. (19), we determine the regions of quantum backflow and the results are given in Fig. (1).

As expected from Eq. (27), the backflow area changes only radially. To understand how the parameters contribute to the value of \( a_B \) we have to study Eq. (13) with \( \omega = 0 \). Approaching the value \( B_{\text{cr}} \), backflow extends radially to infinity, since \( \Omega \) tends to zero and thus \( a_B \) tends to infinity, in the limit of small magnetic field the dominant contribution to \( \Omega \) is due to the parameter \( \eta \) which is constant, in the limit of large magnetic field we return to the commutative case. This is evident if we look at Fig.(2) where the backflow area has been plotted as a
function of the magnetic field. The unit of area has been chosen as a fixed value of $a_{Br}$, where $\eta = 10^{-25} m_r^2 c^2$ to be able to make a comparison between areas at different values of the magnetic field. The magnetic field is expressed in units $B_r$, where $\eta = 10^{-25} m_r^2 c^2$.

Next we consider a (normalized) superposition of eigenfunctions consisting of a larger number, $N$, instead of just 3 as in Eq. (24) of angular momentum eigenstates of the form

$$\Psi_0(r, \varphi) = \frac{1}{\sqrt{N}} \sum_{m=0}^{N-1} c_m(r) e^{-im\varphi} \quad (29)$$

that is a linear combination of $N$ components with non positive angular momentum ($E_{m\leq 0}^c = -\hbar n \leq 0$). The coefficients $c_m(r)$ are defined as in Eq. (25). In the $\omega = 0$ setting we get the results shown in Fig. (3) by repeating the same steps we already showed for the case of three eigenfunctions. We note that the behaviour of this system is exactly the same as in the previous case, and thus we come to the conclusion that, for $n = 0$, the equation that gives us the points $(r, \varphi)$ for which $m_{\text{eff}}$ passes through zero, can always be written in the form $f(r/a_B, \varphi) = 0$, where $f$ will be given by a function similar to that given in Eq. (27) but with a larger number of terms since we are here considering a state $\Psi$ with $N = 11$ components, as in Eq. (29). Therefore compared to the results in [19]—solid line in Fig. (3)—, the shape of the region with backflow is similar to the noncommutative case (dashed line) but with the radial extension being mostly affected when changing the value of the magnetic field.

![FIG. 1. Plot of the region (shaded area) where $m_{\text{eff}} > 0$ in the $(r, \varphi)$ plane for the commutative case (blue) and the non-commutative case with $\eta/m_r^2 c^2 = 10^{-25}$ (orange) with $\omega = 0$. The values of the magnetic field are $B/B_{cr} = 0.1$ (a), $B/B_{cr} = 0.6$ (b), $B/B_{cr} = 0.9$ (c), $B/B_{cr} = 10$ (d). The radial distance, $r$, is in units of $a_B$.](image1)

![FIG. 2. Plot of the backflow area (in units of $a_{Br}$) as a function of the magnetic field for a state with three components as in Eq. (24) and for two values of the parameter $\eta$ with $\omega = 0$, $\eta_1 = 10^{-25} m_r^2 c^2$ (dashed line), $\eta_2 = 3 \times 10^{-25} m_r^2 c^2$ (dot-dashed line) compared to the commutative result (solid line).](image2)

![FIG. 3. Plot of the region (shaded area) where $m_{\text{eff}} > 0$ in the $(r, \varphi)$ plane for the commutative case (blue) and the non-commutative case with $\eta/m_r^2 c^2 = 10^{-25}$ (orange) with $\omega = 0$ for a state with $N = 11$ components as in Eq. (29). The values of the magnetic field are: (a) $B/B_{cr} = 0.1$, (b) $B/B_{cr} = 0.6$, (c) $B/B_{cr} = 0.9$, (d) $B/B_{cr} = 10$. The radial distance, r, is in units of $a_B$.](image3)

B. Model with Oscillator Interaction: $\omega \neq 0$

In this section we shall analyze the effect of the oscillator interaction on the angular momentum backflow. It may be noted that when an oscillator interaction is
present, a critical field cannot be defined as before: At least in the sense that there is no value of $B$ that makes the Hamiltonian $H$ in Eq. (12) that of a free particle. The value $B_{cr}$ in this case simply minimizes the quantity $\beta$ in Eq. (11c) and thus $\Omega$. We can therefore say that the field $B_{cr}$ minimizes in this instance the interaction.

Nonetheless for the sake of convenience we shall make our plots with respect to $B/B_{cr}$.

First of all we note that the infinite degeneracy for fixed $n$ and non positive values of $m$ is no longer present when considering the oscillator interaction. Indeed from Eq. (16b) we see that, when $\theta = 0$, $\omega_0 \to \infty$, $\alpha \to 1$, $\Omega = \sqrt{3} \to \gamma$ and so when $m \geq 0$ there is degeneracy with respect to $m$. Clearly such degeneracy is lifted when the oscillator frequency $\omega \neq 0$ because in this case $\Omega = \sqrt{3} \neq \gamma$. This in turn introduces a time dependence in the wavefunction of Eq. (24) because each component will have now a different energy eigenvalue. This in turn leads to a time dependence of the effective magnetic quantum number $m_{eff}$ and leads to:

\[
m_{eff}(r, \varphi, t) = -\frac{c_1^2 + 2c_2^2 + c_0c_1 \cos \left(\varphi + (\epsilon_{-1} - \epsilon_0) \frac{t}{\hbar} \right) + 3c_1c_2 \cos \left(\varphi + (\epsilon_{-2} - \epsilon_{-1}) \frac{t}{\hbar} \right) + 2c_0c_2 \cos \left(2\varphi + (\epsilon_{-2} - \epsilon_0) \frac{t}{\hbar} \right)}{c_0^2 + c_1^2 + c_2^2 + 2c_0c_1 \cos \left(\varphi + (\epsilon_{-1} - \epsilon_0) \frac{t}{\hbar} \right) + 2c_1c_2 \cos \left(\varphi + (\epsilon_{-2} - \epsilon_{-1}) \frac{t}{\hbar} \right) + 2c_0c_2 \cos \left(2\varphi + (\epsilon_{-2} - \epsilon_0) \frac{t}{\hbar} \right)},
\]

where $\epsilon_m = \epsilon_{0,m}$. The time dependence reduces to a translation of the angle in $m_{eff}$. This effect is shown explicitly in Fig. (4) where we plot the backflow region in the $(r, \varphi)$ plane for two different time values – see caption of figure. We show the region for $t = 0$ (delimited by the dashed curve) which corresponds exactly to the time independent case of Eq. (26) while the solid curve delimits the $\varphi$ shifted one corresponding to Eq. (30). The area of the quantum backflow area will be the same.

Next we show in Fig. 5 the area of the quantum backflow regions as function of the external magnetic field expressed in units of the critical magnetic field $B_{cr}$ given by Eq. (19). In Fig. 5 the solid line is the value of the area of the quantum backflow region when the oscillator interaction is absent. At $B = B_{cr}$ the system becomes free and the region where there is backflow is infinite. On the contrary when the oscillator interaction is present the quantity $\beta$ in Eq. (11b) does not vanish and thus the system is always bounded and the backflow region is always finite. The larger the oscillator frequency $\omega$ the stronger this effect (smaller area) as we can see by comparing in Fig. 5 the dashed line ($\omega = 0.3 \omega_\eta$) and the dot-dashed line ($\omega = \omega_\eta$).

**IV. BACKFLOW PROBABILITY**

In the previous sections we have essentially visualized the amount of quantum backflow by showing the area in the $(r, \varphi)$ plane where the effective angular momentum becomes positive having considered a quantum state built out of components with only non positive values of $m$. We have also compared various scenarios by computing numerically the backflow area. Nevertheless it would be clearly interesting to have a quantitative estimate of the quantum backflow. One of the ways to obtain this estimate is to introduce the concept of probability associated with angular momentum backflow. While in the case of one dimensional problems the issue of the backflow probability has been discussed at length [5, 13, 39, 40], it has not been studied within the context of a two-dimensional interacting systems. Perhaps this was due to the diffi-

![FIG. 4. Plot of the region (shaded area) where $m_{eff} > 0$ for two values of time (orange), compared to the result at $t = 0$ (blue), in the $(r, \varphi)$ plane. The values of time are $t_o = \frac{\hbar}{\epsilon_{-1} - \epsilon_0}$ and $t_b = \frac{2\pi}{\epsilon_{-1} - \epsilon_0}$, where $t_2\pi = 2\pi \frac{\hbar}{\epsilon_{-1} - \epsilon_0}$ is the time relative to a $2\pi$ shift, which depends on the magnetic field. Here we consider the case with the oscillator $(\omega = 0.8 \omega_\eta$ with $\eta/m_0^2 c^2 = 10^{-25}$) for a single value of the magnetic field. The radial distance, $r$, is in units of $a_B$.

![FIG. 5. Plot of the backflow area (in units of $a_B^2$) for a state with three components as in Eq. (24) or as in Eq. (29) with $N = 3$, as a function of the magnetic field (in $B_{cr}$ units where $\eta = 10^{-25} m_0^2 c^2$), for two values of the oscillator frequency $(\omega_0 = 0.3 \omega_\eta$ (dashed line), $\omega_2 = \omega_\eta$ (dot-dashed line)) compared to the result without oscillator (solid line).](image-url)
cullies stemming from the two-dimensional nature of the problem.

A particularly useful approach for the computation of the total backflow probability has been proposed in [13]. In this approach a quantum state built with only positive momenta relates the total backflow probability, for a one-dimensional problem, to the fraction of the $x$ axis where the local wave number $k(x)$ becomes negative. Here we extend this concept to the case of an interacting two-dimensional problem. Our state $\Psi(r, \varphi)$ defined in Eq. (24) is a linear combination of eigenfunctions (16a) with non positive values of the angular momentum ($L_z^{\text{can}}$ component) or non positive values of the magnetic quantum number $m$ ($m \leq 0$). In our problem the analog of the local wave number $k(x)$ of [13] is the local angular momentum ($L_z^{\text{can}}$ component) $\ell(r) = \hbar m_{\text{eff}}(r)$. For a system for which the positions $\mathbf{r}$ are distributed according to a normalizable probability distribution $|\Psi(\mathbf{r})|^2$, the probability distribution of the angular momentum is:

$$P(\ell) = \int \int |\Psi(\mathbf{r})|^2 \delta (\ell(r) - \ell) \, d^2 \mathbf{r}. \tag{31}$$

The above relation can be understood noting that $P(\ell) d\ell$ is the probability of having an angular momentum between $\ell$ and $\ell + d\ell$, and this can be estimated by averaging over the positions $\mathbf{r}$ for which $\ell(r) = \ell$ which are distributed according to $|\Psi(\mathbf{r})|^2$.

It is convenient, in the following, to define a probability density with respect to the angular momentum (magnetic) quantum number $m = \ell/\hbar$. This is easily done by extracting the constant $\hbar$ from the $\delta$-function and defining $P(m) = \hbar P(\ell)$:

$$P(m) = \int \int |\Psi(\mathbf{r})|^2 \delta (m_{\text{eff}}(\mathbf{r}) - m) \, d^2 \mathbf{r}. \tag{32}$$

So that the total backflow probability (probability of having a positive $m$) is obtained as:

$$P_{\text{backflow}} = \int_0^\infty P(m) \, dm. \tag{33}$$

Inserting Eq. (32) into Eq. (33) and making use of the fact that the Dirac $\delta$-function is the derivative of the Heaviside $\theta$-function we obtain:

$$P_{\text{backflow}} = \int \int |\Psi(\mathbf{r})|^2 \, d^2 \mathbf{r} \left\{ - \frac{\partial}{\partial m} \theta (m_{\text{eff}}(\mathbf{r}) - m) \right\} \, dm = \int \int |\Psi(\mathbf{r})|^2 \, d^2 \mathbf{r} \left[ - \theta (m_{\text{eff}}(\mathbf{r}) - m) \right]_{m=0}^{m=+\infty} = \int \int |\Psi(\mathbf{r})|^2 \theta (m_{\text{eff}}(\mathbf{r})) \, d^2 \mathbf{r} \tag{34}$$

We may finally write the total angular momentum backflow probability as:

$$P_{\text{backflow}} = \int_0^{+\infty} \int_0^{2\pi} \theta (m_{\text{eff}}(r, \varphi)) \, |\Psi(r, \varphi)|^2 \, r \, dr \, d\varphi, \tag{35}$$

where $\Psi(r, \varphi)$ are the normalized eigenfunction.

We have computed the total angular momentum backflow probability $P_{\text{backflow}}$ evaluating numerically the integral in Eq. (35) first for an effective angular momentum defined in Eq. (26) for the state as in Eq. (24) with a number of components $N = 3$, and subsequently for states defined as in Eq. (29) with increasing number of components up to $N = 6$.

We have also examined the variation of the probability of quantum backflow with respect to different choices of the associated weights $c_m$ with a given number of components $N$. The results of the computations are given in Table I where we see that $P_{\text{backflow}}$ varies somewhat as the number of components of the state, $N$, is increased and, within a fixed $N$, as configurations with different weights $c_m$ are considered. In some cases ($N = 3, 5, 6$) it appears that the configurations with $c_0$ the largest weight have a higher probability relative to the configurations where weights other than $c_0$ are largest but we were unable to generalize it. For instance this does not happen for $N = 4$. This may be traced to the fact that the region where $m_{\text{eff}} > 0$ is strongly dependent on the different choices of the weights and also on the different values of $N$ as we have explicitly observed. Also, as $N$ increases, the computation becomes increasingly challenging from the numerical point of view. We have verified that, as expected, for any state with given number of components, $N$, and any configurations of the coefficients $c_m$, the backflow probability is independent of the magnetic field $B$ computing $P_{\text{backflow}}$ for two different values of the magnetic field. In retrospect the independence of the total angular momentum backflow probability from the external magnetic field can be understood also from Eq. (20) and Eq. (22). Indeed we see that the term $\mathbf{j}_2$ in the total current, which depends explicitly on the magnetic field (vector potential) does not contribute to $m_{\text{eff}}$. On the other hand from the explicit expression of the exact wave-functions (c.f. Eq. (16)) the only other dependence on the magnetic field is through the quantity $a_B$. Given that the wave functions depend only on $(r/a_B, \varphi)$ and that $|\Psi(r)|^2 \propto a_B^2 f(r/a_B, \varphi)$ it can be easily shown from Eq. (35) that the total backflow probability is independent of the magnetic field $B$. Let us also remark that while the results in Table I have been computed for $\omega = 0$, choosing an oscillator interaction $\omega \neq 0$ simply changes the value of $a_B$ but not $P_{\text{backflow}}$ since we have shown that the probability is $a_B$ independent.

V. DISCUSSION AND CONCLUSIONS

In this article we have studied the noncommutative generalization of the angular momentum backflow problem considered in [19]. Extending the exact solution of a free charged particle in a homogeneous magnetic field, we have also considered angular momentum backflow when an oscillator interaction is present. Subsequently we also included momentum noncommutativity only so
as to avoid gauge invariance issues associated with noncommuting space coordinates [31]. It has been found that the area where angular momentum backflow takes place changes with the magnetic field which in turn depends on the noncommutativity parameter.

Next, we have attempted to give a quantitative description of the angular momentum backflow. We adopted the approach developed in [13] where in a one-dimensional problem the total probability of momentum backflow is related to the fraction of the x-axis where the local wave number $k(x)$ is negative (within a state consisting only of components with positive wave numbers). We therefore extend the above approach [13] to our two-dimensional problem of a charged Dirac particle in a magnetic field. More precisely, in analogy with [19] we considered a (normalized) physical state $\Psi(r)$ consisting of a linear combination of eigenfunctions with non positive magnetic angular momentum values ($m \leq 0$), c.f. Eq. (24) and relate the probability of backflow to an average, over the probability density distribution $|\Psi(r)|^2$, of the area of the region of the plane where $m_{\text{eff}} \geq 0$, c.f. Eq. (33) and Eq. (35). It has been found that total probability of angular momentum backflow remains the same for different values of the magnetic field. In other words, the backflow probability is independent of the magnetic field.

It might be noticed that our study of the backflow regions is based on the analysis of the quantity $m_{\text{eff}}$ defined in Eq. (22a,22b) and as such it is not a gauge invariant quantity because only the total current $j$ of Eq.(19) is gauge invariant while $j_1$ and $j_2$ are gauge variant. So quantities obtained as averages over the effective local angular momentum $m_{\text{eff}}(r, \varphi)$ such as the expectation value of the canonical angular momentum $\langle \psi | L_z^{\text{can}} | \psi \rangle = \int d^2r m_{\text{eff}}(r, \varphi) |\psi|^2$ would be gauge variant. This might worry the reader that our conclusions on the angular momentum backflow depend on the gauge choice. However this is not the case as there is a well known subtlety concerning the gauge invariant definition of the orbital angular momentum in the Landau problem [41–44]. Indeed it has been shown that a gauge invariant orbital angular momentum $L_z$ can be defined in terms of the canonical angular momentum $L_z^{\text{can}} = (r \times p)_z$ via $L_z = L_z^{\text{can}} + \frac{\xi r A_\varphi}{\varepsilon} - \frac{\xi}{\varepsilon} B r^2$ [43]. However it turns out that in the symmetric gauge, used throughout this work, the additional contribution $\frac{\xi r A_\varphi}{\varepsilon} - \frac{\xi}{\varepsilon} B r^2$ vanishes identically and the expectation values of $L_z^{\text{can}}$, computed with $m_{\text{eff}}$ coincide with the expectation values of the gauge invariant $L_z$. Going to another gauge, for instance the Landau gauge, the change in $\langle L_z^{\text{can}} \rangle$ will be compensated by the change in $\langle (\frac{\xi r A_\varphi}{\varepsilon} - \frac{\xi}{\varepsilon} B r^2) \rangle$ as to obtain the same result of the symmetric gauge. By the same token other observable quantities computed, in the symmetric gauge from $m_{\text{eff}}$ such as, for instance, the back-flow probability, are gauge invariant.

We have also examined the dependence of the quantum backflow probability with respect to the number of components ($N$) in the wave packet as well as the associated weights $c_m$, finding that it can reach values as high as $P_{\text{backflow}} \approx 0.2$. More precisely in the present paper we have considered states of the system which are either (i) only a simple sum of the $N$ eigenstates with a fixed value of the radial quantum number $(n = 0)$ or (ii) a sum of $N$ components (again with $n = 0$) with various choices of different weights $c_m$. We have not been able to identify a well defined and general pattern of $P_{\text{backflow}}$ when higher values of the number of components $N$ are considered, both in configurations with equal and different weights $c_m$. Other possibilities could of course be considered, but they would go beyond the scope of the present work. Here we were mainly interested in presenting a sensible definition of the angular momentum backflow probability for the problem of a charged particle in a constant homogeneous magnetic field, with and without the oscillator interaction, along with a complete and exact solution, of the same problem, also in the pres-

\end{table}
ence of non-commutative coordinates. One interesting feature that emerges from our analysis is that the angular momentum backflow probability in our two-dimensional system reaches, in some cases, values ($P_{\text{backflow}} \approx 0.2$) that are larger than the maximum allowed value found by Braken and Malloy $c_{\text{om}} \approx 0.04$ for a one-dimensional free system. This may be quite important in view of upcoming experimental studies of the quantum backflow.

In conclusion in this paper we have been able to confirm the angular momentum backflow of a non-relativistic charged particle in a magnetic field even in the presence of non-commutative coordinates. We also succeeded in defining and computing explicitly the angular momentum backflow probability, $P_{\text{backflow}}$, going beyond the results of ref. [19] by extending to a two-dimensional physical system the approach developed in [13] for momentum backflow in a one-dimensional system.

It is the authors’ opinion that these findings are of interest for further developments in the subject of quantum backflow.
