Background and Objectives: The aim of this study was to investigate the factors associated with decrease in speech discrimination ability seen in patients with presbycusis and whether aging has a significant effect on the observed decline. Subjects and Methods: We retrospectively analyzed the medical records of patients aged >40 years who had undergone pure-tone audiometry, speech audiometry, and auditory brainstem response for hearing loss at our hospital from January 2019 to June 2021, and investigated the factors that correlated with speech discrimination score. Results: We enrolled 103 patients with 120 ears, with a mean age of 65.8±11.9 years. The pure-tone average of the patients’ thresholds at 0.5, 1, 2, and 4 kHz was 37.2±27.7 dB HL, and their mean speech discrimination score was 82.5%±22.3%. A correlation analysis revealed a significant negative correlation between the patients’ speech discrimination scores and age. In addition, all variables of pure-tone audiometry and the patients’ auditory brainstem responses were significantly correlated with the speech discrimination scores. The pure-tone average had the strongest negative correlation. On analyzing the significant predictors of lower speech discrimination scores, using a multiple linear regression analysis, pure-tone average and age showed significant results. Conclusions: The speech discrimination ability of older patients with hearing loss significantly decreases with increasing pure-tone average and age.

Keywords: Presbycusis; Speech discrimination; Aging; Auditory perceptual disorder.
Subjects and Methods

We retrospectively analyzed the medical records of 103 patients aged >40 years who had undergone PTA, speech audiometry, and ABR for hearing loss at our hospital from January 2019 to June 2021. In all, 120 ears were analyzed, excluding those with problems with the middle ear cavity or tympanic membrane, such as chronic otitis media, or with a history of inner ear disease, such as sudden hearing loss or Meniere’s disease. Patients with a history of genetic diseases related to hearing loss, autoimmune diseases, or taking anticancer drugs were also excluded.

We investigated the factors that correlated with speech discrimination score. Analyses included patient age, pure-tone average, and amplitude and latency of waves I and V in the ABR.

PTA was performed using a clinical audiometer (GSI61™; Grason-Stadler Inc., Eden Prairie, MN, USA) calibrated according to the standards of the International Organization for Standardization. Pure-tone air and bone conduction audiograms were analyzed at 0.5, 1, 2, and 4 kHz. Speech discrimination was scored in terms of the percentage of phonetically balanced words that were correctly identified from the Hahm’s monosyllabic word list [4].

We measured the amplitude and latency of ABR waves I and V at 90 dB normalized hearing level (nHL) in the tested ears using Navigator pro EP (Bio-Logic Systems Corp., Mundein, IL, USA) and a click sound for stimulation. The output interval was adjusted by 10 dB nHL, and the output range was set at 20–90 dB nHL. The active electrode was placed in the parietal region, the reference electrode was attached to both mastoid processes, and the ground electrode was attached to the forehead. Two-channel electrodes were used for the recordings. The resistance values were adjusted to ≤5 kΩ.

After identifying the factors correlated with the speech discrimination score, significant predictors of the score were identified through linear regression analysis.

Statistical analyses

Pearson correlation analysis was used to investigate the correlation between speech discrimination and other variables, and linear regression analysis was applied to investigate significant predictors of the speech discrimination score. For all statistical analyses, we used SPSS software (ver. 20.0; IBM Corp., Armonk, NY, USA); p values <0.05 were considered statistically significant.

Ethics statement

The study protocol was reviewed and approved by the Institutional Review Board of Catholic University (IRB number: DC21RISI0046). The requirement for informed consent was waived by the board.

Results

The mean age of the patients was 65.8 ± 11.9 years, the mean pure-tone average was 37.2 ± 27.7 dB HL, and the mean speech discrimination ability was 82.5% ± 22.3% (Table 1). The average latencies of ABR waves I and V were 1.62 ± 0.27 ms and 5.69 ± 0.44 ms, respectively, and the average amplitudes were 0.10 ± 0.07 μV and 0.17 ± 0.09 μV, respectively. Because the average age of the patients was high, 21.7% had diabetes, 36.7% had hypertension, and 12.5% had tinnitus. The mean threshold of the PTA for each frequency showed a down-sloping pattern in which the threshold increased as the frequency increased (Fig. 1).

In correlation analyses, there was a significant negative correlation between speech discrimination score and age (Fig. 2). There were no significant differences in the average speech

| Characteristics                        | Value (n=120 ears) |
|----------------------------------------|--------------------|
| Sex (male:female)                      | 49:71              |
| Side (right:left)                      | 60:60              |
| Age (yr)                               | 65.8 ± 11.9        |
| Diabetes mellitus                      | 26 (21.7%)         |
| High blood pressure                    | 44 (36.7%)         |
| Tinnitus                               | 15 (12.5%)         |
| Pure-tone average, 0.5, 1, 2, 4 kHz (dB HL) | 37.2 ± 27.7       |
| Speech reception threshold (dB HL)     | 32.0 ± 24.3        |
| Speech discrimination score (%)        | 82.5 ± 22.3        |
| ABR wave I amplitude (μV)              | 0.10 ± 0.07        |
| ABR wave V amplitude (μV)              | 0.17 ± 0.09        |
| ABR wave I latency (ms)                | 1.62 ± 0.27        |
| ABR wave V latency (ms)                | 5.69 ± 0.44        |
| ABR, auditory brainstem response       |                    |

Effect of Aging on Speech Discrimination

speech discrimination score according to the presence or absence of chronic disease or tinnitus (data not shown). Comparing speech discrimination score and other hearing test variables, all variables including the PTA threshold for each frequency and speech discrimination score were significantly correlated, and the mean pure-tone average (0.5, 1, 2, and 4 kHz) showed the strongest negative correlation (Table 2). In addition, the speech discrimination score and amplitudes of ABR waves I and V showed a significant positive correlation, whereas the latencies of waves I and V showed a negative correlation. When the significant predictors of speech discrimination score were analyzed through multiple linear regression analysis, the pure-tone average and age showed significant results (Table 3). However, the amplitude or latency of ABR waves I and V were not significant predictors of the speech discrimination score.

### Discussion

The speech discrimination ability of older patients with AHL was significantly reduced by an increase in the pure-tone average and increase in age. There is a consensus that problems with understanding speech in older adults are the result of deteriorated functioning of the cochlea and age-related declines in central auditory processing [5-8]. Our results showed that age and pure-tone average were significant predictors of the speech discrimination score (Table 3). Based on the beta coefficient, the pure-tone average affected speech discrimination scores much more than age. In other words, deterioration of cochlear function had a greater effect on speech discrimination than age-related decline of central auditory processing.

Studies have reported that a decrease in hearing sensitivity is the major factor influencing the decrease in speech discrimination [9,10]. In a study of Japanese-speaking presbycusis patients, the pure-tone average thresholds at 125 Hz and 8,000 Hz had a negative correlation with speech discrimination for monosyllabic words; the pure-tone average, which showed 50% of speech discrimination, was 76.4 dB HL [10]. Another study of German-speaking patients found that a pure-tone average of 60 dB HL corresponded to a speech discrimination score of 50% [11]. In our study, the pure-tone average threshold at 500 Hz and 4,000 Hz was 82.6 dB HL, which corresponded to 50% speech discrimination, showing a slightly higher value than the previous results. This is probably due to the different languages and the ages of the subjects included in each study.

However, the most interesting question of this study was whether an increase in age had a significant effect on a decrease in speech discrimination regardless of a decrease in hearing sensitivity. The results showed that increasing age had a significant effect on speech discrimination, probably due to a decrease in the function of central auditory processing with aging (Fig. 2, Table 3). We evaluated the age-related decline in central auditory processing function at the brain stem level by ABR, but there was no significant causal relationship between the change in ABR and speech discrimination in the results of

### Table 2. Correlation analysis between speech discrimination and other hearing test variables

| Variables                        | Correlation coefficient | p    |

regression analysis.

As shown in Table 2, the ABR parameters showed a significant correlation with speech discrimination scores. In patients with high speech discrimination scores, the ABR amplitude tended to be higher and the latency to be shorter. Previous studies have shown that the ABR amplitude and latency changed significantly with aging, regardless of the deterioration of hearing sensitivity [12]. Many studies have reported that the ABR amplitude decreases and latency increases with aging [13-15].

As mentioned above, aging-related deficits in central auditory processing are associated with reduced speech discrimination. In previous studies, the latency of the cortical auditory evoked potential (CAEP) waveform was significantly increased in patients with low speech discrimination ability [16,17]. Another study found that reduced ABR wave I amplitude, an indicator of cochlear neuronal degeneration, was associated with decreased speech perception ability in noise among older patients [18]. In our study, it was difficult to find a meaningful causal relationship between ABR results and speech discrimination. However, the significant correlation between increasing age and decreasing speech discrimination ability implies that aging negatively affects central auditory processing, leading to a decrease in speech discrimination. Defective central auditory processing is difficult to evaluate with a single hearing test, and should be comprehensively identified through several tests including ABR, CAEP, and cognitive exams.

In conclusion, the speech discrimination ability of older patients with hearing loss significantly decreased with an increase in the pure-tone average and age; of the two, the decrease in hearing sensitivity is the more important factor.
