Abstract

Phytohormones play important roles in plant acclimation to changes in environmental conditions. However, their role in whole-plant regulation of growth and secondary metabolite production under increasing atmospheric CO2 concentrations ([CO2]) is uncertain but crucially important for understanding plant responses to abiotic stresses. We grew winter wheat (Triticum aestivum) under three [CO2] (170, 390, and 680 ppm) over 10 weeks, and measured gas exchange, relative growth rate (RGR), soluble sugars, secondary metabolites, and phytohormones including abscisic acid (ABA), auxin (IAA), jasmonic acid (JA), and salicylic acid (SA) at the whole-plant level. Our results show that, at the whole-plant level, RGR positively correlated with IAA but not ABA, and secondary metabolites positively correlated with JA and JA-Ile but not SA. Moreover, soluble sugars positively correlated with IAA and JA but not ABA and SA. We conclude that increasing carbon availability stimulates growth and production of secondary metabolites via up-regulation of auxin and jasmonate levels, probably in response to sugar-mediated signalling. Future low [CO2] studies should address the role of reactive oxygen species (ROS) in leaf ABA and SA biosynthesis, and at the transcriptional level should focus on biosynthetic and, in particular, on responsive genes involved in [CO2]-induced hormonal signalling pathways.

Key words: Abscisic acid, auxin, elevated CO2, jasmonic acid, low CO2, salicylic acid, secondary metabolites, soluble sugars.

Introduction

Plants capture CO2 from the atmosphere and convert it into sugars as essential building blocks for growth and substrates for metabolism (Hartmann and Trumbore, 2016). Atmospheric CO2 concentrations ([CO2]) has risen from ~170–200 ppm during glacial periods to the current 400 ppm, and are predicted to reach between 430 ppm and 1000 ppm by 2100 (Cubasch et al., 2013). Understanding the mechanisms by which increasing [CO2] have influenced whole-plant growth and metabolism in the past will help to unravel mechanisms regulating plant responses to future elevated [CO2] but also to reduced carbon availability as may occur during shading, cold, or drought. Phytohormones play an important
role in plant acclimation to changing environmental conditions (Peleg and Blumwald, 2011), such as drought (Valluru et al., 2016) and salinity (Albacete et al., 2008). However, our understanding of how phytohormones, such as auxin, abscisic acid (ABA), jasmonic acid (JA), or salicylic acid (SA), are involved in the whole-plant regulation of plant gas exchange, growth, and secondary metabolite (SM) production under changing [CO₂] is still limited.

ABA plays a role in multiple physiological processes for stress acclimation. For example, ABA is the main regulator of stomatal responses to drought and salinity (Osakabe et al., 2014). Elevated [CO₂] reduces stomatal conductance and density (Franks et al., 2013), and this is often (Lake and Woodward, 2008; Chater et al., 2015), but not always (Teng et al., 2006; Merilo et al., 2013) associated with increased leaf ABA concentration. Changes in carbohydrate availability have been proposed to be a sensing pathway by which plants may increase ABA biosynthesis at elevated [CO₂] (Chater et al., 2014). Additional application of glucose can increase ABA biosynthesis (reviewed in León and Sheen, 2003), and the ABA-dependent signalling pathway is essential for sucrose-induced stomatal closure (Kelly et al., 2013). Moreover, the activation of the ABA signalling pathway is involved in inhibition of root growth under osmotic stress (Achard et al., 2006; Rowe et al., 2016).

Auxin (indole-3-acetic acid; IAA) was recognized as an essential plant growth promoter >70 years ago (Enders and Strader, 2015), but much less is known about its role in modulating plant response to abiotic stress (Kazan, 2013). Elevated CO₂ increased carbohydrate and IAA concentrations and promoted growth in Arabidopsis thaliana (Teng et al., 2006; Hachiya et al., 2014) and tomato seedlings (Solanum lycopersicum; Wang et al., 2009) but reduced IAA concentrations in roots of sweet pepper (Capsicum annuum; Piñero et al., 2014). Niu et al. (2011) showed that the auxin-dependent signalling pathway is required for enhancing root development under elevated CO₂ in Arabidopsis. Moreover, accumulated soluble sugars may be key elicitors for increased IAA production under elevated [CO₂], as both glucose (Sairanen et al., 2012) and sucrose additions (Lilley et al., 2012) have been shown to stimulate IAA biosynthesis and resulted in higher growth rates in the latter study. In contrast, low [CO₂] reduces carbohydrate availability (Hartmann et al., 2013, 2015) and limits plant growth (Gerhart and Ward, 2010), but whether IAA regulation is involved in these processes remains uncertain.

JA (Riemann et al., 2015) and SA (Khan et al., 2015) play key roles in regulating plant defence responses to abiotic and biotic stresses. The JA signalling pathway involves the isoleucine (Ile) conjugate of JA (JA-Ile), a phytohormone that activates the transcription of JA-dependent defence genes (Thines et al., 2007). In contrast to JA-Ile, the hydroxylated derivatives of JA, such as 12-hydroxy-JA (12-OH-JA, tuberonic acid) may deactivate JA-dependent defence genes (Miersch et al., 2008; Koo and Howe, 2012). Elevated [CO₂] has been shown to enhance SA-dependent defence and repress JA-dependent defence (Zavala et al., 2013; Sun et al., 2016), but how plants regulate JA and SA at low [CO₂] remains uncertain. Furthermore, changes in soluble sugars may regulate production of SMs via modulation of JA and SA. Sucrose (Loreti et al., 2008) and glucose (Guo et al., 2013) play a synergistic role with JA in anthocyanin and glucosinolate biosynthesis, respectively.

Shading and defoliation are common approaches for reducing plant sugar availability, but shading can activate IAA biosynthesis (Casal, 2013) and suppress JA biosynthesis via changes in phytochromes (Ballare, 2014), and defoliation itself is a wounding treatment that can trigger JA biosynthesis with cascading effects on other phytohormones (Erb et al., 2012). Directly manipulating [CO₂] suffers less from such side effects and allows plants to regulate phytohormones under contrasting carbon (rather than light) availability.

Here, we present an analysis of whole-plant phytohormone dynamics in winter wheat (Triticum aestivum) grown along a gradient of atmospheric CO₂ concentrations (170, 390, and 680 ppm). We investigated correlations between phytohormone concentrations and stomatal conductance, relative growth rate (RGR), and soluble sugar and SM concentrations. In this study, we focused on ABA, IAA, SA, and JA as well as its derivatives JA-Ile and 12-OH-JA, although we are aware that other phytohormones such as cytokinin and ethylene also play important roles in the regulation of growth. Based on knowledge about hormonal regulation of growth and secondary metabolite production at the tissue/organ level, we explore whether the following relationships hold true at the whole-plant level: with increasing [CO₂], plants (i) reduce stomatal conductance via increasing ABA; (ii) promote growth via increasing IAA; (iii) increase biosynthesis of SMs via increasing JA, JA-Ile, and SA; and (iv) show higher carbohydrate concentrations that, in turn, induce the biosynthesis of phytohormones.

Materials and methods

Plant material

We used a cultivar of winter wheat (Triticum aestivum cv. Genius) adapted to Central Europe. On 7 January 2015, seeds were germinated on plates filled with sand and watered every day. After 6 d, we transplanted 10–12 seedlings with similar height into each pot (11 cm diameter, 24 cm height) pre-filled with quartz sand. Six pots were randomly placed in each growth chamber. All pots were irrigated with a continuous through-flow of a modified Hoagland solution (Hoagland and Arnon, 1950).

Growth chambers and treatments

Plants were grown in glass chambers (75 cm long×45 cm wide×80 cm high) flushed continuously with air at a flow rate of 14 l min⁻¹ (for more details, see Hartmann et al., 2013). Concentrations of the different CO₂ treatments were produced by first scrubbing all CO₂ from incoming air using a molecular sieve, and then injecting pure CO₂ (Schnyder, 1992). The [CO₂] of incoming air for the three [CO₂] treatments was measured with a Vaisala® (GMP 343) at intervals of 10 min. A micro-logger (Campbell® CR1000) compared these concentrations against pre-set values (170, 390, and 680 ppm) and adjusted them accordingly via mass flow controllers. For each [CO₂] treatment, three chambers were used to grow plants and one chamber was used to monitor [CO₂] reference levels.

In each chamber, we monitored air temperature and photosynthetic photon flux density (PPFD) continuously (for more details,
During the day, average temperature increased from ~12 °C at 06:30 h (local time) to ~20–24 °C and then decreased to ~16.5 °C at 22:00 h. Plants were grown in a light/dark regime of 16/8 h using supplemental greenhouse lamps. The average PPDF from 23 January 2015 to 20 March 2015 was 7.79 ± 0.92 mol m⁻² d⁻¹.

Destructive harvesting

To rule out potential effects of plant development on hormone levels, we harvested plants in different treatments independently of calendar dates and when three, six, and eight leaf sheaths were completely developed, denoted as 3L, 6L, and 8L periods, respectively. The experiment was only conducted during the vegetative growth period (seedling growth and tillering stage). Plants grown in 390 ppm and 680 ppm [CO₂] chambers were sampled 3, 7, and 9 weeks after transplanting, whereas plants grown in low [CO₂] chambers were sampled 3.5, 8, and 10.5 weeks after transplanting. Harvests were always conducted between 16:00 h and 21:00 h to minimize light and temperature effects on hormones and metabolites. For each harvest, we removed one pot from each chamber. Plants were separated into leaves, stems, and roots. Leaf area was determined with a Li 3100A area meter (Li-Cor, Bad Homburg, Germany). All fresh tissues were weighed and frozen in liquid nitrogen and later transferred to a −80 °C freezer. Around 75% of the biomass was freeze-dried, weighed, and ground to fine powder using a ball mill (Retsch® MM400, Haan, Germany) and finally stored at −20 °C until further analysis. The rest of the samples were ground with liquid nitrogen using a mortar and pestle, and stored at −80 °C until analysis.

Whole-plant gas exchange

A Picarro® 2101-i (precision 0.01–0.4%, Picarro Inc., Santa Clara, CA, USA) was used to measure the [CO₂] and [H₂O] of air entering and leaving the growth chambers. The air coming from the 12 chambers and the reference air were measured sequentially at intervals of 6 min 40 s; the cycle was controlled by a micro-logger (Campbell® CR1000) connected to a custom-built valve switching unit, completing a whole cycle within 2 h. Transition periods after valve switching were excluded from analysis.

We assumed whole-plant gas exchange to be constant within the 2 h cycle. The instantaneous whole-plant assimilation (A) and transpiration (E) at hour j was calculated as:

\[
[\text{CO}_2 \text{ or } \text{H}_2 \text{O}]_{\text{non-plant}} - \frac{[\text{CO}_2 \text{ or } \text{H}_2 \text{O}]_{\text{plant}}}{M} \left(\text{umol} \text{mol}^{-1}\right) \times \frac{VFR(\text{min}^{-1})}{22.4(\text{mol} \text{kg}^{-1}) \times 60 \text{s}}
\]

(1)

where \([\text{CO}_2 \text{ or } \text{H}_2 \text{O}]_{\text{non-plant}}\) and \([\text{CO}_2 \text{ or } \text{H}_2 \text{O}]_{\text{plant}}\) is the [CO₂ or H₂O] of outgoing air from the reference chambers without plants and from chambers with plants, respectively. M represented the number of plants in the chamber, and VFR was the volumetric flow rate of air going through the chamber (141 min⁻¹). The value of 22.4 l mol⁻¹ is the molar volume of gas under normal conditions. Canopy conductance was then estimated as previously described in McDowell et al. (2008):

\[
G_s = \frac{E}{\text{VPD}}
\]

(2)

where VPD (kPa) is vapour pressure deficit. Note that the relative humidity of incoming air was very low (<2%) therefore VPD is close to the saturation vapour pressure at chamber temperature. Leaf area-based (i.e. specific) net assimilation, transpiration, and stomatal conductance (Gs) were then calculated by dividing instantaneous whole-plant exchange by leaf area (m²).

Analysis of soluble sugars

Concentrations of glucose, sucrose, and fructose were measured using the method of Raessler et al. (2010). Briefly, we added 1 ml (0.5 ml for small samples) of sterilized water to 50 mg (10 mg for small samples) of ground sample. The mixture was vortexed, incubated for 10 min at 65 °C, and then centrifuged for 10 min at 12 000 g. The supernatant was carefully collected and stored on ice, and the pellet was re-extracted twice. The supernatants were pooled and diluted at a ratio of 1:20 (1.8 for small samples) and stored at −20 °C before measurements. Sucrose, glucose, and fructose were determined by HPLC coupled with pulsed amperometric detection (HPLC-PAD), on a Dionex® ICS 3000 ion chromatography system equipped with an autosampler (Thermo Fisher GmbH, Idstein, Germany).

Analysis of SMs

A 500 µl aliquot (300 µl for small samples) of 95% methanol was added to 50 mg (30 mg for small samples) of freeze-dried tissues. The mixture was head-beaten for 40 s at 6.0 m s⁻¹ with a FastPrep Instrument (MP Biomedicals, Santa Ana, CA, USA), vortexed for 5 min, and then centrifuged at 13 000 g for 5 min. The supernatant was collected and the pellet was re-extracted. The supernatants were pooled and stored at 4 °C. Identification and quantification of SMs were achieved by HPLC coupled with MS and a UV Detector. Phenolic compounds were separated on a Nucleodur Sphinx RP18ec column (250 × 4.6 mm, particle size 5 μm, Macherey Nagel, Dueren, Germany) with two mobile phases 0.2% (v/v) formic acid (A) and acetonitrile (B) using the following elution profile: 0–28 min, 5–61% B in A; 28–30 min 100% B; and 30–35 min 5% B. Flow was diverted in a ratio of 4:1 before entering the mass spectrometer electrospray chamber. For identification, ESI-MS was operated at a negative mode scanning m/z between 50 and 1600 with an optimal target mass of 400 m/z. The MS conditions were: skimmer voltage, 60 V; capillary voltage, 4200 V; nebulizer pressure, 35 psi; drying gas, 11 l min⁻¹; gas temperature, 330 °C; capillary exit potential, −121 V. For quantification, the UV wavelengths 240, 260, 280, and 330 nm were monitored. Compounds of leaves and stems were identified by comparing the fragmentation patterns with previously reported wheat phenolic profiles (Moheb et al., 2011; Wojakowska et al., 2013). Root compounds were identified based on profiles of benzoxazinoids in grasses (Wouters et al., 2014). All compounds were quantified by external standards (for more details, see Huang et al., 2016).

Quantification of hormones

Concentrations of ABA, IAA, SA, and jasmonates, comprising JA, JA-Ile, and 12-OH-JA, were determined using the method of Vadassery et al. (2012) with modifications. Briefly, 250 mg of fresh samples were extracted with 1 ml of methanol containing 40 ng of D₃-ABA (Santa Cruz Biotechnology, Santa Cruz, CA, USA), 40 ng of D₃-IAA (Olechmin, Olomouc, Czech Republic), 40 ng of D₃-SA (Sigma-Aldrich), 40 ng of D₃-JA (HPC Standards GmbH, Cunnersdorf, Germany), and 8 ng of JA-[¹³C]Ile conjugate as internal standards. JA-[¹³C]Ile was synthesized using [¹³C]Ile (Sigma-Aldrich) according to Kramell et al. (1988). The mixture was vortexed for 10 min and then centrifuged at 13 000 g for 10 min. A 800 µl aliquot of the supernatant was then collected and transferred into a 5 ml 96-well plate. The pellet was re-extracted with 500 µl of methanol using the same procedure, and 500 ml of supernatant was collected, pooled, and stored at −20 °C.

Hormone detection and quantification was accomplished with an Agilent 1260 HPLC system (Agilent Technologies,
Santa Clara, CA, USA) coupled to an API 5000 tandem mass spectrometer (Applied Biosystems, Foster City, CA, USA) equipped with a Turbospray ion source. Hormones were separated on a Zorbax Eclipse XDB-C18 HPLC column (1.8 μm, 50 × 4.6 mm; Agilent) at 25 °C, with two mobile phases consisting of 0.05% formic acid in water (solvent A) and acetonitrile (solvent B), at a flow rate of 1.1 ml min⁻¹ using the following elution profile: 0–0.5 min, 10% B; 0.5–4.0 min, linear gradient from 10% to 90% B; 4.0–4.02 min, linear gradient from 90% to 100% B; 4.02–4.50 min, 100% B, 4.50–4.51 min, linear gradient from 100% to 10% B; and 4.51–7.00 min, 10% B. The parent ion and their fragments of jasmonates, SA, and ABA were analysed in negative mode by multiple reaction monitoring (MRM) (for more details, see Vadassery et al., 2012). IAA was analysed in the positive ionization mode in a separate chromatographic analysis (same LC conditions as above for other phytohormones) with the following conditions: analyte parent ion → product ion: m/z 176→130 for IAA; m/z 181→134+ m/z 181→133 for D₃-IAA. Collision energy (CE) was 19 V; declustering potential (DP) was 31 V. Q₁ and Q₃ quadrupoles were both maintained at unit resolution. Mass data were collected and processed using analyst 1.6 software (Applied Biosystems). Linearity in ionization efficiencies was confirmed by analysing serial dilutions of a standard mixture. The concentrations of ABA, IAA, SA, and ABA were determined relative to the corresponding internal standard mixture. The concentrations of ABA, IAA, SA, and ABA were analysed relative to the corresponding internal standard.

Data analysis

Each growth chamber was treated as a biological replicate (n=3). We determined homogeneity of variances with the Levene test and log-transformed data when variance was not homoscedastic. Tukey’s HSD (P<0.05) was used to detect significant differences between treatments. Weighted phytohormone concentrations were calculated by multiplying tissue-specific concentrations by tissue biomass and dividing their sum by whole-plant mass, as for weighted soluble sugars and SM concentrations. Phytohormones were reported on a fresh weight basis; therefore, to ensure consistency of units, the concentrations of soluble sugars and SMs were converted to fresh weight. We assessed the Pearson’s correlation of phytohormones with gas exchange, RGR, soluble sugars, and SMs. All statistical analysis was conducted in R, version 3.2.5 (R Development Core Team, 2014).

Results

Gas exchange rate

Plants grown at 170 ppm [CO₂] exhibited lower assimilation rates but higher transpiration rates and higher stomatal conductance compared with plants grown at 390 ppm and 680 ppm [CO₂] (Fig. 1a–c). The difference between the two higher [CO₂] treatments, however, varied with developmental stages. At 3L, assimilation rates increased significantly at 680 ppm [CO₂] compared with 390 ppm [CO₂], while at 6L and 8L the increase disappeared (Fig. 1a). At 3L and 6L, transpiration rates and stomatal conductance remained relatively constant between 390 ppm and 680 ppm [CO₂], while at 8L they were higher at 680 ppm than at 390 ppm [CO₂] (Fig. 1b, c).

RGR, soluble sugars, and secondary metabolites

Similar to assimilation, plants grown at 170 ppm [CO₂] exhibited a lower RGR of all tissues than plants grown at 390 ppm [CO₂], across developmental stages (Fig. 2a–c). At 6L, RGR was higher in plants grown at 680 ppm [CO₂] than at 390 ppm [CO₂], but at 8L, plants grown at 390 ppm and 680 ppm [CO₂] exhibited a similar RGR of all tissues (Fig. 2a–c).

The [CO₂] response of soluble sugars varied with developmental stages and tissues. At 3L, all soluble sugar concentrations slightly increased at 170 ppm [CO₂] in leaves, but glucose and fructose concentrations significantly decreased in stems and roots, compared with 390 ppm [CO₂] (Fig. 3a–i). At 6L, there was no significant difference in soluble sugars across tissues between 170 ppm and 390 ppm [CO₂], but glucose and fructose concentrations significantly increased at 680 ppm [CO₂] in all tissues compared with 390 ppm [CO₂] (Fig. 3a–i). Interestingly, at 6L, we did not observe large differences in leaf sucrose concentration between the two higher [CO₂] treatments. From 6L to 8L, while soluble sugars of all tissues showed a declining trend at 680 ppm [CO₂], they accumulated at 390 ppm [CO₂] but slightly decreased at 170 ppm [CO₂] (Fig. 3a–i). Sucrose concentrations were

Fig. 1. Leaf area-based net assimilation rate (a), transpiration rate (b), and stomatal conductance of winter wheat (Triticum aestivum) for the three [CO₂] treatments (squares, 680 ppm; circles, 390 ppm; triangles, 170 ppm). Values are the mean ±SE of three individual chambers. Filled symbols of 680 ppm [CO₂] treatments indicate significant differences compared with 390 ppm [CO₂] treatment (P<0.05, Tukey’s HSD). We harvested plants after emergence of three, six, and eight leaf sheaths, denoted by 3L, 6L, and 8L, respectively. (This figure is available in colour at JXB online.)
Hormonal regulation of growth and secondary metabolites

much higher in leaves than in stems and roots, whereas glucose and fructose concentrations were generally higher in stems (Fig. 3a–i).

At 3L, plants grown at contrasting [CO₂] showed similar SM concentrations in leaves and roots. However, at 6L and 8L, leaf SM concentrations decreased with declining...
[CO₂], but the decrease was greater at 170 ppm (compared with 390 ppm) than at 390 ppm (compared with 680 ppm). In contrast, at 6L and 8L, root SM concentrations remained unchanged between 390 ppm and 680 ppm [CO₂] treatments, but they were lower at 170 ppm than at 390 ppm and 680 ppm [CO₂], although not statistically significant at 8L (Table 1).

### Hormonal profiling

At 6L and 8L, IAA concentrations decreased at 170 ppm [CO₂] in all tissues compared with 390 ppm and 680 ppm [CO₂], but the difference between the two higher [CO₂] treatments varied with developmental stages and tissues (Fig. 4a–c). IAA concentrations in stems were generally twice more than those in leaves and roots (Fig. 4a–c). In contrast to IAA, at 3L and 6L, ABA concentrations increased at 170 ppm [CO₂] in leaves but not in stems and roots, compared with 390 ppm and 680 ppm [CO₂] (Fig. 4d, e). From 3L to 8L, a consistent decrease in leaf ABA concentrations was observed at 170 ppm [CO₂], while the opposite was the case for 390 ppm and 680 ppm [CO₂] treatments (Fig. 4d). Note that ABA concentrations were much lower in roots than in leaves and stems (Fig. 4d, e).

Similar to IAA, at 6L and 8L, JA and JA-Ile concentrations were much lower in plants grown at 170 ppm than at 390 ppm and 680 ppm [CO₂], but at 6L there was no difference in leaves and stems between these two higher [CO₂] treatments (Fig. 5a–e). Plants grown at contrasting [CO₂] exhibited relatively similar 12-OH-JA concentrations in leaves and stems (Fig. 5g–i). Note that leaves and stems had lower concentrations of JA and JA-Ile but higher concentrations of 12-OH-JA compared with roots, in particular at 390 ppm and 680 ppm [CO₂] (Fig. 5a–i).

In contrast, plants grown at 170 ppm [CO₂] had higher leaf SA concentrations than at 390 ppm and 680 ppm [CO₂] (Fig. 6a). However, at 3L and 8L, there were no differences between the two higher [CO₂] treatments, and only at 6L were leaf SA concentrations lower at 390 ppm [CO₂] than at 680 ppm [CO₂] (Fig. 6a). SA concentrations remained relatively constant in stems and roots across [CO₂] treatments (Fig. 6b, c). Note that SA concentrations were relatively lower in stems and roots than in leaves (Fig. 6a–c).

### Correlations of phytohormones to RGR, stomatal conductance, SMs, and soluble sugars

As expected, the decline in whole-plant RGR with decreasing [CO₂] was positively correlated with weighted IAA concentrations ($R^2=0.84$, $P=0.01$) (Fig. 7a). In contrast, RGR was negatively correlated with weighted ABA concentrations ($R^2=0.15$), but not statistically significantly (Fig. 7b). There was no correlation between stomatal conductance and leaf ABA concentrations (Fig. 7c). Weighted SM concentrations were also positively correlated with weighted JA concentrations ($R^2=0.79$, $P=0.02$) as well as concentrations of its bioactive derivative JA-Ile ($R^2=0.51$, $P=0.11$), but not with weighted SA concentrations (Fig. 7d, f). We also found a significant positive correlation between weighted soluble sugar concentrations and weighted IAA and JA concentrations, but not weighted ABA and SA concentrations (Fig. 8a–d).

### Discussion

Manipulating whole-plant carbon availability along a gradient of [CO₂] combined with whole-plant hormonal analysis allowed unravelling of the mechanisms by which plants cope with abiotic stresses. As summarized in Fig. 9, our study revealed that low [CO₂] increased ABA and SA concentrations in leaves, probably in order to cope with potential oxidative stress from excess light excitation energy. With increasing C availability, wheat plants increased growth and

### Table 1. Secondary metabolite concentrations in leaves, stems, and roots of winter wheat (Triticum aestivum) for the three [CO₂] treatments: 680 ppm [CO₂], 390 ppm [CO₂], and 170 ppm [CO₂]

Values are mean [µg g⁻¹ FW] ±SD of three individual chambers. Note that the concentrations are expressed on a fresh weight basis.

Different letters indicate significant differences between [CO₂] treatments ($P<0.05$, Tukey’s HSD). We harvested plants after emergence of three, six, and eight leaf sheaths, denoted by 3L, 6L, and 8L, respectively. DIMBOA-Glc, 2-(6,4-dihydroxy-7-methoxy-1,4-benzoazin-3-one)-β-D-glucopyranoside; HDMOBA-Glc, 2-(6-hydroxy-4,7-dimethoxy-1,4-benzoazin-3-one)-β-D-glucopyranoside. See also supporting information from Huang et al. (2016).
SM production via increases in IAA and JA (JA-Ile) levels and probably triggered by sugar signalling pathways.

Stomatal regulation

Transpiration rates and stomatal conductance were higher at low [CO$_2$] than at ambient and elevated [CO$_2$], and this difference increased over time. However, contrary to our expectation, stomatal conductance was not associated with leaf ABA concentrations under contrasting [CO$_2$]. Although it is well established that ABA can induce stomatal closure (Osakabe et al., 2014), a lack of response to changes in bulk ABA cannot rule out ABA-dependent stomatal regulation, as mutants with only 10% of wild-type ABA concentrations showed stomatal closure under elevated [CO$_2$] (Merilo et al., 2013). A recent study of ABA-deficient plants suggested that stomatal regulation under elevated [CO$_2$] requires increases in ABA in both stomatal precursor cells and guard cells, rather than in bulk ABA (Chater et al., 2015). Furthermore, increasing leaf ABA concentration between 3L and 8L at elevated [CO$_2$] may be due to a down-regulation of stomatal density under elevated [CO$_2$] (Chater et al., 2014).

Growth regulation

RGR increased in all tissues with increasing [CO$_2$] and were, at the whole-plant level, positively correlated with IAA but not with ABA, suggesting that IAA may be involved in growth regulation under low C availability. Growth modulation via IAA has also been observed under elevated [CO$_2$] in Arabidopsis (Hachiya et al., 2014) and in tomato seedlings (Wang et al., 2009), and during drought and low temperatures in rice (Oryza sativa) (Zhang et al., 2009; Du et al., 2013).

While leaves, stems, and roots showed similar RGR, IAA concentrations in stems were more than twice as high as in leaves and roots. IAA is synthesized mainly in the shoot apex and then transported to roots (Ljung et al., 2001) so high IAA concentrations in stems may be an inactive transitory pool. Moreover, the basipetal transport of IAA from shoot to roots remained relatively constant even under low C availability, as the ratio of stem to root IAA concentrations remained relatively constant across [CO$_2$] treatments. In addition, at 8L, when RGR and soluble sugar concentrations at elevated [CO$_2$] declined in all tissues to ambient [CO$_2$] levels, we also observed a decrease in stem IAA concentrations. This decrease highlights the potential role of IAA in photosynthetic acclimation (Xu et al., 2015), especially under elevated [CO$_2$].

We observed a weak relationship between RGR and ABA, and inconsistent temporal changes across tissues, suggesting that bulk ABA is not a main regulator for tissue growth. However, the ratio of leaf to stem ABA was, throughout the experiment, consistently higher at low than at ambient [CO$_2$], possibly because ABA is involved in photosynthetic acclimation to low [CO$_2$]. However, our data set cannot provide deeper insights into this mechanism, and assessments of other parameters, such as enhanced production of reactive oxygen species (ROS) from excess excitation energy at

Fig. 4. Auxin (IAA) (a–c) and abscisic acid (ABA) concentrations of winter wheat (Triticum aestivum) for the three [CO$_2$] treatments (squares, 680 ppm; circles, 390 ppm; triangles, 170 ppm). Values are the mean (ng g$^{-1}$ FW) ±SE of three individual chambers. Filled symbols of 680 ppm and 170 ppm [CO$_2$] treatments indicate significant differences compared with 390 ppm [CO$_2$] treatment (P<0.05, Tukey’s HSD). Note that the concentrations are expressed on a fresh weight basis and at different scales. We harvested plants after emergence of three, six, and eight leaf sheaths, denoted by 3L, 6L, and 8L, respectively. (This figure is available in colour at JXB online.)
Fig. 5. Jasmonic acid (JA) (a–c), the isoleucine (Ile) conjugate of JA (JA-Ile) (d–f), and 12-hydroxy-JA (12-OH-JA) (g–i) concentrations of winter wheat (*Triticum aestivum*) for the three [CO$_2$] treatments (squares, 680 ppm; circles, 390 ppm; triangles, 170 ppm). Values are the mean (ng g$^{-1}$ FW) ±SE of three individual chambers. Filled symbols of 680 ppm and 170 ppm [CO$_2$] treatments indicate significant differences compared with 390 ppm [CO$_2$] treatment ($P<0.05$, Tukey’s HSD). Note that the concentrations are expressed on a fresh weight basis and at different scales. We harvested plants after emergence of three, six, and eight leaf sheaths, denoted by 3L, 6L, and 8L, respectively. (This figure is available in colour at *JXB* online.)

Fig. 6. Salicylic acid (SA) (a–c) concentrations of winter wheat (*Triticum aestivum*) for the three [CO$_2$] treatments (squares, 680 ppm; circles, 390 ppm; triangles, 170 ppm). Values are the mean (ng g$^{-1}$ FW) ±SE of three individual chambers. Filled symbols of 680 ppm and 170 ppm [CO$_2$] treatments indicate significant differences compared with 390 ppm [CO$_2$] treatment ($P<0.05$, Tukey’s HSD). Note that the concentrations are expressed on a fresh weight basis. We harvested plants after emergence of three, six, and eight leaf sheaths, denoted by 3L, 6L, and 8L, respectively. low \([\text{CO}_2]\) (Galvez-Valdivieso et al., 2009), are required to elucidate the role of ABA in stress mitigation (Mittler and Blumwald, 2015).

**Regulation of secondary metabolite synthesis**

Low \([\text{CO}_2]\) reduced leaf flavonoids and root putrescine-based compounds as well as root benzoxazinoid derivatives, and this response was strongly associated with reduced JA and its bioactive derivative JA-Ile. Jasmonates are involved in the biosynthesis of a wide range of SMs including flavonoids (Gundlach et al., 1992), putrescine (Horbowicz et al., 2011), and benzoxazinoid derivatives (Oikawa et al., 2002). That low \([\text{CO}_2]\) reduced SM synthesis via down-regulation of JA-dependent pathways is corroborated by evidence that deficiencies in potassium (Troufflard et al., 2010) and phosphate (Khan et al., 2016) can enhance SM production via up-regulation of JA and JA-Ile in Arabidopsis (Troufflard et al., 2010; Khan et al., 2016). In contrast, SA concentrations were higher in leaves at low than at ambient \([\text{CO}_2]\), indicating that low C availability reduces leaf SM production independent of the SA signalling pathway. Given that SA and JA are antagonistic (Zavala et al., 2013; Sun et al., 2016), it is possible that the up-regulation of SA signalling is associated with the suppression of JA signalling at low C availability.

In contrast, under elevated \([\text{CO}_2]\), leaf JA and SA levels changed independently from each other across developmental stages but both may nonetheless play a role in regulation of SMs. At 6L, leaf flavonoids and SA concentrations increased under elevated \([\text{CO}_2]\) but that was not the case for JA and JA-Ile, indicating that elevated \([\text{CO}_2]\) may stimulate short-term leaf flavonoid synthesis via SA (Zavala et al., 2013; Sun et al., 2016). At 8L, however, plants grown at elevated \([\text{CO}_2]\) had higher leaf JA and JA-Ile concentrations than at ambient \([\text{CO}_2]\) and probably induced flavonoid production. These dynamics mirror a potential long-term acclimation of photosynthesis at elevated \([\text{CO}_2]\), as indicated by declines in RGR and soluble sugars in all tissues at elevated \([\text{CO}_2]\). Deeper insights into such long-term leaf acclimation to elevated \([\text{CO}_2]\) via hormonal regulation require assessments of hormones and SMs over the entire plant developmental gradient.

In roots, however, while SMs and SA remained relatively constant, JA and JA-Ile concentrations were higher at elevated \([\text{CO}_2]\) than at ambient \([\text{CO}_2]\). We suggest here that JA-dependent signalling for SM production in roots was probably constrained by N availability, given that root SMs are N-rich compounds and that assimilation of nitrate into
organic N compounds may be limited under elevated [CO$_2$] (Bloom et al., 2010). Therefore, N availability, rather than JA- and JA-Ile-dependent signalling, determined the response of root SMs to elevated [CO$_2$].

**Potential sugar signalling for IAA and JA synthesis**

Soluble sugars are essential substrates for growth and metabolism (Hartmann and Trumbore, 2016), but also act as signalling molecules that interact with plant hormones to mediate plant stress responses (Rolland et al., 2006; Lastdrager et al., 2014). Our results revealed that accumulation of soluble sugars with increasing [CO$_2$] positively correlated with weighted IAA and JA concentrations, allowing our experiment to demonstrate nicely the interaction of soluble sugars and IAA and JA at the whole-plant level. It has been shown that glucose (Sairanen et al., 2012) and sucrose (Lilley et al., 2012) can both stimulate IAA biosynthesis and growth rates. In contrast, jasmonates reduced glucose and fructose concentrations in *Nicotiana attenuata* leaves (Machado et al., 2015) and play a synergistic role with sucrose (Loreti et al., 2008) and glucose (Guo et al., 2013) in anthocyanin and glucosinolate biosynthesis. Hence, it is more likely that accumulation of soluble sugars at high [CO$_2$] stimulated whole-plant IAA and JA synthesis rather than vice versa. This sugar signalling pathway may also be a mechanism that triggers IAA and JA biosynthesis under cold, drought, and nutrient limitation, as these stresses decrease growth earlier than photosynthesis, thus allowing surplus carbon to be allocated to carbohydrates (Herms and Mattson, 1992; Palacio et al., 2014). In contrast to IAA and JA, soluble sugars were not correlated with weighted ABA and SA concentrations, possibly because low [CO$_2$] may trigger leaf ABA and SA biosynthesis via signalling pathways independent of sugar availability, for example ROS accumulation from excess excitation energy and photorespiration (Galvez-Valdivieso et al., 2009; Herrera-Vásquez et al., 2015).

Light intensities (8 mol m$^{-2}$ d$^{-1}$) were much lower in the greenhouse than usually occur in the field, and it might be that plants grown at ambient and elevated [CO$_2$] were light limited. However, the general agreement of plant responses in our study with results from field experiments downplays the importance of light limitation. Moreover, higher light intensities in the field are likely to amplify CO$_2$-induced responses, such as increases in assimilation, sugars, RGR, and secondary metabolites, as well as corresponding IAA and JA levels. Consequently, the suboptimal light conditions in the greenhouse underscore the robustness of our findings as the observed patterns are likely to be more pronounced in field-grown plants.

**Outlook**

Our study is an initial step towards unravelling whole-plant hormonal regulation of growth and defence in response to changing [CO$_2$] including low [CO$_2$]. We hypothesize that low

Fig. 9. Conceptual model and research needs of whole-plant hormonal regulation in response to changing [CO₂], derived from our experimental results and published literature. The leaf cross-section figure was modified from an original figure provided by Zephyris (Richard Wheeler) and Wikipedia. Increased [CO₂] stimulates photosynthesis and results in accumulation of soluble sugars at the whole-plant level which may elicit a cascade of downstream IAA and JA regulation of plant growth and defence, respectively. Increasing [CO₂] may dissipate the reducing power from the photosynthetic electron transfer chain and reduce photorespiration, which theoretically reduce ROS production (Salvez-Valdivieso et al., 2009). Low [CO₂]-induced ROS accumulation may trigger ABA (Mittler and Blumwald, 2015) and SA biosynthesis (Herrera-Vásquez et al., 2015), which in turn promote ROS accumulation or scavenging. Low [CO₂] could increase translocation of ABA from mesophyll chloroplast to guard cells and, as reported by Chater et al. (2015), the increase in guard cell ABA is sufficient to reduce stomatal conductance and density. Up-regulation of SA signalling may be associated with suppression of JA signalling (Zavala et al., 2013; Sun et al., 2016). Interactive signalling pathways via sugars for growth regulation and synthesis of secondary metabolites but also transport and distribution of phytohormones across tissues are still uncertain. Soluble sugars may stimulate IAA via the PIF family of transcription factors (Lilley et al., 2012; Sairanen et al., 2012). Furthermore, IAA may induce the GH3 family which in turn catalyses the conjugation of IAA to amino acids (Sauer et al., 2013). IAA and JA may stimulate growth and SM production via degradation of the repressor Aux/IAA (Enders and Strader, 2015) and JAZ (Riemann et al., 2015), respectively. ABA, abscisic acid; IAA, auxin; JA, jasmonic acid; JAZ, jasmonate ZIM-domain protein; PIF, phytochrome-interacting factor; ROS, reactive oxygen species; SA, salicylic acid; SMs, secondary metabolites; SS, soluble sugars. Green arrows indicate positive, red negative, and brown uncertain.

Further progress in our understanding of hormonal whole-plant growth regulation can be achieved by combining measurements of bulk tissue hormone concentrations with investigations on hormone distribution and translocation across different tissues/organs. For example, root growth and development is regulated by auxin that has been synthesized in the shoot apex and transported to root tips to result in local auxin concentration peaks (Peer et al., 2011). Similarly, ABA is stored mainly in the mesophyll cell, but a recent study shows that only ABA concentrations in guard cells control stomatal responses to elevated [CO₂] (Chater et al., 2015). Experiments with mutants will provide more direct evidence for causality in hormonal regulation, and future studies at the transcriptional level should focus on biosynthetic and, in particular, responsive genes involved in hormonal signalling pathways. For example, soluble sugars may stimulate IAA via the phytochrome-interacting factor (PIF) family of transcription factors (Lilley et al., 2012; Sairanen et al., 2012). Auxin-responsive GH3 (Du et al., 2012, 2013) and Aux/IAA genes (Jung et al., 2015), and the JA-responsive jasmonate ZIM-domain (JAZ) gene family (Du et al., 2013; Riemann et al., 2015) are signalling repressors and have been shown to be involved in drought and cold tolerance.

Acknowledgements

The authors thank Olaf Kolle, Waldemar Ziegler, and René Schwalbe for their assistance in [CO₂] manipulation, Savoyane Lambert and Iris Kuhlmann for their assistance in sample processing, and Jessica Heublein for the measurements of soluble sugars. We also thank Susan Trumbore and Jonathan Gershenzon for their support with the measurements of secondary metabolites and phytohormones.
