Cucurbit[7]uril inclusion complexation as a supramolecular strategy for color stabilization of anthocyanin model compounds†

Barbara Held,‡a Hao Tang,‡b Palani Natarajan,§b Cassio Pacheco da Silva,a Volnir de Oliveira Silva,a Cornelia Bohne*b and Frank H. Quina*b

Host–guest complexation with cucurbit[7]uril of anthocyanin model compounds in which acid–base equilibria are blocked resulted in essentially complete stabilization of their color. The color protection is a thermodynamic effect and establishes a strategy to stabilize these colored compounds at pH values of interest for practical applications.

Introduction

Anthocyanins are the natural plant pigments responsible for the majority of the red, blue and purple colors of fruits, flowers, and leaves.1 The basic chromophore of anthocyanins is the flavylum cation, whose color depends primarily on the substituents present on the chromophore and the local pH.2 Above about pH 3 in aqueous solution, however, the flavylum cation form (Fl+) of anthocyanins typically undergoes hydration to form the hemiacetal (B), followed by ring-opening tautomerization to give the Z-chalcone (CZ) and subsequent isomerization to the E-chalcone (CE). These equilibria are indicated in Scheme 1 for the 3′,4′,7-trimethoxyflavylum ion (B-TMF), together with the structure of the 7-methoxy-4-methylflavylum cation (MMF+), a compound that does not hydrate under the same conditions.3

In nature, the color of anthocyanins can be stabilized to some extent by complexation with metal cations or colorless organic molecules, called co-pigments.4,5 Guest-host complexation is an alternative strategy that might potentially preserve the color of the flavylum cation chromophore more effectively than co-pigmentation by shielding the chromophore from contact with water. Achieving the stabilization of the colored flavylum cation is relevant to the ways in which flavylum ions, and by inference anthocyanins, can potentially be stabilized as photoprotectors.4,5 Guest-host complexes with hosts such as molecular clips6 and cucurbit[7]uril (CB[7])7–9 were shown to slow down the decoloration rate. In this context, cucurbiturils are particularly attractive as hosts since they have a high affinity for cationic species10–12 and can change the spectroscopic properties and reactivity of guest molecules that are included in their interior.13–17 CB[7] complexation of flavylum cations containing a hydroxyl group at the 7-position resulted in only partial color stabilization because the decrease of the rate of the hydration reaction was offset by the deprotonation of the flavylum cation at higher pH.7–9 We report here that the flavylum cation form (Fl+) of B-TMF, in which the acid–base equilibria are blocked, indeed exhibits an impressive, essentially complete stabilization against hydration upon inclusion in a 1 : 2 guest-host complex with CB[7]. Kinetic

experiments showed that this is a thermodynamic and not a kinetic effect.

**Experimental**

MMF$^+$ was synthesized as previously described.$^{18}$ The modified synthesis for B-TMF$^{19,20}$ and CB$[7]^{21-23}$ and the titration of CB$[7]^{24}$ are described in the ESI (Fig. S1 and S2 in the ESI† for B-TMF). Cobaltocenium hexafluorophosphate (Cob$^+$ PF$_6^-$, Aldrich 98%), HCl (Anachemia, ACS reagent grade) and methanol (EMD Emulsol, spectrograde) were used as received. Deionized water (Barnstead Nanopure System, ≥ 17.8 MΩ cm) was used for all aqueous solutions. B-TMF stock solutions (1.1 mM) were prepared either in acidified methanol (pH = 0.6) or by directly dissolving the solid in water containing 1 mM HCl. Stock solutions of CB$[7]$ were prepared in 1 mM HCl aqueous solutions. Binding isotherm determinations and stopped-flow experiments were performed in the presence of 1 mM HCl. The initial concentrations for the stopped-flow experiments were 0.4 µM of B-TMF and between 0 and 12.6 µM of CB$[7]$. Separate solutions of B-TMF and CB$[7]$ were mixed in the stopped-flow experiment in a 1 : 1 ratio and the final concentrations were one half of the initial ones. The B-TMF and MMF$^+$ concentrations for the binding isotherms were 0.2 µM. The methods for the fitting of the binding isotherms are described in the ESI.$^\dagger$

The kinetic absorption experiments on the minutes time scale at pH values of 4.3 and higher were performed with 5.0 µM B-TMF. Two different experiments were performed: (i) B-TMF was injected into aqueous solutions without and with CB$[7]$. (ii) B-TMF was pre-incubated in water at pH 4.6 for 12 h. After this period the solution was injected with water (control) or aqueous CB$[7]$ solutions. Spectra were collected at regular intervals or the kinetics were followed at 470 nm, where Fl$^+$ absorbs.

The apparent hydration constant (pK$_{ap}$) was determined by adding B-TMF (18 µM) to solutions prepared at different pH values and measuring the absorption spectra 2 h and 24 h after the B-TMF addition.

Absorption spectra were measured with Cary 100 UV-Vis or Cary 50 Bio spectrometers, or a Hewlett Packard 8452A diode array spectrometer. Kinetic studies at 470 nm, where Fl$^+$ absorbs, were performed on the Cary 100 or Cary 50 Bio spectrometers where multi-cell holders were used (6 to 18) and the absorption was measured sequentially at defined intervals.

Fluorescence measurements with B-TMF were performed with a PTI QM-2 fluorimeter with excitation and emission monochromator bandwidths of 5 nm. The samples were excited at 470 nm and the emission spectra were measured between 500 and 700 nm. The spectrum of a water sample was subtracted from the experimental fluorescence spectra to remove the Raman scattering peak of water at ca. 560 nm. The experiments were performed at 20 °C. Fluorescence measurements with MMF$^+$ were measured with a Hitachi F-4500 where the bandwidths for the excitation and emission monochromators were 5.0 nm. The samples were excited at 416 nm and the emission spectra were measured between 430 and 650 nm. No spectral subtraction was required in this case because the Raman scattering was negligible. The experiments were performed at 25 °C.

Stopped-flow experiments were performed with a SX20 system from Applied Photophysics. Samples were excited at 470 nm using a 2.3 nm bandwidth on the excitation monochromator, and the emission was detected at 90 degrees with respect to the excitation beam using a 515 nm cut-off filter. The two syringes, one containing B-TMF and the other with CB$[7]$, were kept at 20 °C for 10 min before the start of mixing. The mixing ratio was 1 : 1. Each experiment corresponds to the average of 24 individual kinetic traces. The control experiments were the following: (i) mixing of two water solutions to determine the “zero” reading and (ii) the mixing of water with B-TMF to determine the fluorescence intensity of B-TMF in the absence of CB$[7]$. The kinetic data were analyzed using the Pro-Data Viewer software from Applied Photophysics. The quality of the fits was judged by the randomness of the residuals. All the kinetics fit well to a mono-exponential function.

**Results and discussion**

In the absence of CB$[7]$ in aqueous solution at ca. pH 1, the dominant form of B-TMF is the Fl$^+$ form, with a maximum absorption at 470 nm. Transfer to a solution of pH 4.3 results in spectral changes characteristic of the hydration and subsequent ring-opening tautomerization and isomerization reactions, since B, C$_Z$ and C$_E$ do not absorb above 400 nm (Fig. 1). From the pH dependence of the loss of the color of the Fl$^+$ form, a value of pK$_{ap}$ = 3.0 ± 0.3 was found for the negative logarithm of the apparent hydration constant (inset Fig. 1, see
That this is a true thermodynamic rather than a mere kinetic stabilization of the flavylium cation form Fl⁺ of B-TMF was shown by initially incubating B-TMF (5 µM) at pH 4.6 for 12 h to obtain an equilibrium mixture containing predominantly the hydration product B plus C₂ and C₆. Addition of 12 µM or 120 µM CB[7] then resulted in a shift of the equilibrium toward Fl⁺ (Fig. 3B) at a rate and to an extent dependent on the concentration of added host (Fig. S5 in the ESI† for fluorescence measurements). It is important to note that the kinetics after incubation for 12 h are not the same as those for the direct addition of B-TMF to a solution of CB[7] where the effect of the slow conversion of C₂ to C₆ is absent.

The binding kinetics of guests with cucurbiturils can be fast, with relaxation processes that occur in the sub-second to seconds time-domain.26–28 The binding kinetics were studied by stopped-flow, accompanying the increase in fluorescence due to the complexation of Fl⁺ upon mixing of a solution of B-TMF with a solution containing CB[7] (Fig. 4, top). The kinetics levelled off within 0.25 s showing the formation of the CB[7] complex. The formation of B, C₂ and C₆ was not observed on this time scale. The experiments were run under conditions where the concentration of CB[7] was at least 10 times higher than the concentration of Fl⁺ and all kinetic traces fit well to first-order kinetics. Although both Fl⁺ and B were initially present in solution ([HCl] = 1 mM) at the time of mixing, the kinetic traces showed no initial offset that would indicate a fast process occurring within the stopped-flow mixing time of 1 ms, which could be related to the binding of B. Therefore under the pseudo-first order conditions used, the

![Fig. 2](image1.png)

Absorption spectra at pH 4.3 measured 7 h after the addition of B-TMF (5 µM) in the absence (black) and presence of 12 µM (blue) and 120 µM (red) CB[7]. The inset shows the spectra right after the addition of B-TMF. For 120 µM CB[7], the spectra are still unchanged 7 h after the addition of B-TMF.

Fig. 3 Kinetics measured at 470 nm for B-TMF (5 µM) at pH 4.6. A: after addition of B-TMF to an aqueous solution without added CB[7] (black) or addition to aqueous solutions of B-TMF containing 12 (blue) or 120 µM CB[7] (red). B: after addition of water (black), or 12 (blue) or 470 µM CB[7] (red) to B-TMF pre-incubated for 12 h at pH 4.6.

![Fig. 4](image3.png)

Fig. 4 Top: Stopped-flow kinetics for the mixing of B-TMF (0.2 µM) with CB[7] (top to bottom: 6.3 µM (red), 4.2 (black), 2.1 (green), 1.0 (blue) and 0 (red)). The lowest trace (black) corresponds to the baseline intensity for water in the mixing cell. Bottom: Dependence of the observed rate constant with the concentration of CB[7] for two independent experiments (black and red symbols) fit simultaneously to eqn (1). Error bars not shown are smaller than the data points.
concentration of B is not relevant for the analysis of the kinetic data.

The kinetics of Fl+ binding with CB[7] could not be followed at concentrations of CB[7] above 7 µM because the reaction rate exceeded the time-resolution of the equipment (rate constant >600 s⁻¹). In the accessible time range, the observed first-order rate constants were a linear function (eqn (1)) of the CB[7] concentration (Fig. 4 bottom), providing values for the bimolecular association (k₁₁) and unimolecular dissociation (k₁₁⁻) rate constants of (7.7 ± 0.2) × 10⁷ M⁻¹ s⁻¹ and 50 ± 10 s⁻¹. The ratio of these values leads to an equilibrium constant of (1.5 ± 0.3) × 10⁶ M⁻¹, which was assigned to the formation of the 1:1 complex between Fl+ and CB[7] (K₁₁), because at the low CB[7] concentrations the formation of the 1:2 complex is negligible since K₁₂ is much lower than K₁₁ (see below). Two relaxation processes would have been observed if the rate constants for hydration/dehydration were of the same order as those for complex formation. The values of k₁₁+ and k₁₁⁻ for B-TMF were estimated to be ca. 0.05 s⁻¹ and 10⁴ M⁻¹ s⁻¹, respectively, from the value of pK₁₁ and the values reported by Pina et al. for analogous compounds. Thus, at pH 3, k₁₁⁺[H⁺] should be ca. 10 s⁻¹, which is at least an order of magnitude smaller than the lowest value of kobs measured.

\[ k_{\text{obs}} = k_{11+}[\text{CB}[7]] + k_{11-} \]  

Because the fluorescence intensities of the Fl⁺ form of B-TMF and MMF⁺ increase upon addition of CB[7] (Fig. S6 in the ESI), the changes in fluorescence were used to obtain the binding isotherms. The binding isotherm for B-TMF could not be fit with a model that considered the formation of only a 1:1 complex (Fig. 5). The intensity decrease observed for the calculated fit for a 1:1 stoichiometry at high CB[7] concentrations occurs because the fluorophore was diluted as CB[7] was added. This dilution was taken into account in the numerical fit. The binding isotherm did however fit nicely to a sequential 1:1 and 1:2 B-TMF:CB[7] binding stoichiometry. Because the emission efficiencies of the 1:1 and 1:2 complexes were similar, the equilibrium constants derived from the unrestrained fits had relatively large errors. For this reason, the value for K₁₁ determined from the kinetic studies (1.5 × 10⁶ M⁻¹) was treated as a fixed parameter. This provided a fit with good residuals and an estimated K₁₂ value of ≤3 × 10⁴ M⁻¹ (see ESI for details), showing that the binding of the second CB[7] to Fl+@CB[7] is less efficient than the binding of the first CB[7]. For the objectives of the current work, an absolute value of K₁₂ is not required; the crucial point being the demonstration that the higher order 1:2 complex is indeed formed at the higher CB[7] concentrations and is the key species in the protection of the flavilium cation of B-TMF from hydration. Likewise, fitting of the binding isotherms of MMF⁺ with CB[7] also required the assumption of a 1:2 sequential binding model with K₁₁ = (9 ± 2) × 10⁷ M⁻¹ and K₁₂ = (8 ± 5) × 10⁴ M⁻¹ (Fig. S7 in the ESI). The fact that MMF⁺ does not hydrate under these conditions shows that the formation of the 1:2 complex is a feature of the flavilium cation framework for both MMF⁺ and Fl⁺. The slightly smaller K₁₁ value and much larger K₁₂ value for MMF⁺ compared to B-TMF⁺ are attributed to differences in steric hindrance caused by the 4-methyl substitution in MMF⁺ vs. dimethoxy substitution in the B-ring of B-TMF. The formation of the 1:2 complex between flavilium derivatives and CB[7] in addition to the 1:1 complex was previously not reported. However, the position and hydrophobicity of the substituents were shown to affect the magnitude of the equilibrium constants for the 1:1 complex to determine which ring is primarily incorporated into the CB[7] and the ability of CB[7] to shuttle between the two rings.

The kinetic experiments show that the rate of formation of the 1:1 complex is faster than the hydration reaction (Scheme 2). The rate constant for association of the Fl⁺ form of B-TMF with CB[7] is ca. 4 times higher than that of berberine (Chart 1), a guest with a centrally located positive charge similar to Fl⁺, but one order of magnitude lower than that for the 2-naphthyl-1-ethylammonium cation, in which the positive charge is located at an extremity of the molecule. In contrast, the dissociation rate constants for Fl⁺ and the 2-naphthyl-1-ethylammonium cation were the same, while the value for the larger berberine molecule was ca. 60 times lower.

![Fig. 5](image-url)  
**Fig. 5** Top: Fit of the binding isotherm for B-TMF (0.2 µM) with CB[7] assuming a pK₁₁ of 3.0 to a 1:1 stoichiometry (black, dashed line) and to sequential 1:1 and 1:2 B-TMF:CB[7] stoichiometries (red, solid line). Bottom: Residuals between the data and calculated values for the fits assuming a 1:1 stoichiometry (black) and sequential 1:1 and 1:2 stoichiometries (red).

![Scheme 2](image-url)  
**Scheme 2** Representation of the competitive reactions of B-TMF in the aqueous phase and for incorporation in CB[7].
lower. The intermediate behavior observed for \( \text{Fl}^+ \) suggests that it fits snugly into the \( \text{CB}[7] \) cavity, implying that the larger 1-benzopyrylium moiety is the portion of the molecules that is preferentially included in the 1:1 complex. The inclusion of the remaining portion (the B ring) of the flavylium ion protruding from the 1:1 complex into the cavity of the second \( \text{CB}[7] \), together with steric and/or dipolar repulsion between the two juxtaposed \( \text{CB}[7] \) host molecules would nicely rationalize the weaker 1 : 2 binding.

The selective binding of the \( \text{Fl}^+ \) forms of these two flavylium cations to \( \text{CB}[7] \) is fully consistent with the known preference of \( \text{CB}[7] \) for cationic species over neutral ones,\(^{17,31,32}\) such as the hemiacetal B and the chalcones \( \text{C}_2 \) and \( \text{C}_E \). At the higher \( \text{CB}[7] \) concentrations, where the \( \text{Fl}^+ \) form is sequestered as the 1 : 2 complex, essentially complete protection of the \( \text{Fl}^+ \) form of B-TMF against hydration is observed, even at pH values where hydration is predominant in water. At lower \( \text{CB}[7] \) concentrations, the observation of only partial protection can be ascribed to the competition between the dissociation of \( \text{Fl}^+@\text{CB}[7] \) to yield free \( \text{Fl}^+ \), which can undergo hydration, and the association of the \( \text{Fl}^+@\text{CB}[7] \) with a second \( \text{CB}[7] \) forming an unreactive complex (Scheme 2).

Inhibition of the reactivity of \( \text{CB}[n] \) bound guests has been observed previously,\(^{33-38}\) mainly by protecting the guest from bimolecular reactions with reactants in water. Cucurbituril stabilization of the color of synthetic anthocyanin analogues against reaction with water at pHs of importance in technological applications, such as in the food industry, is a potential strategy with an advantage that cucurbiturils with different cavity sizes could be employed to encapsulate anthocyanidins or minimally glycosylated naturally-occuring anthocyanins of different sizes in the form of 1 : 2 complexes. The stabilization of the different isomers of anthocyanin derivatives is also of importance in the development of photoprotectors active in different wavelengths regions.

Conclusions

Complete stabilization of the color of a flavylium cation was achieved at moderate pH by complexation with \( \text{CB}[7] \). Key to this stabilization is the use of a flavylium cation that does not have the hydroxyl substituent in the 7-position of the flavylium framework and the formation of a 1 : 2 guest-\( \text{CB}[7] \) complex. The formation of this higher order complex ensures that the hydration reaction is non-competitive with the formation of guest-host complex.
