We study the combined effect of delayed Raman response and bit pattern randomness on pulse propagation in massive multichannel optical fiber communication systems. The propagation is described by a perturbed stochastic nonlinear Schrödinger equation, which takes into account changes in pulse amplitude and frequency as well as emission of continuous radiation. We perform extensive numerical simulations with the model, and analyze the dynamics of the frequency moments, the bit-error-rate, and the mutual distribution of amplitude and position. The results of our numerical simulations are in good agreement with theoretical predictions based on the adiabatic perturbation approach.

I. INTRODUCTION

The interplay between noisy phenomena and nonlinear processes is a rich field of research that is of great interest in a variety of disciplines including solid state physics, turbulence, and optics. One of the most important problems in this field concerns propagation of coherent patterns, such as solitons and solitary waves, in the presence of noise and/or disorder. An excellent example for systems where noise and nonlinear effects play an important role in the dynamics of coherent patterns is provided by fiber optics communication systems, which employ optical pulses to represent bits of information. It is by now well established that the parameters characterizing the pulses in fiber optics communication systems can exhibit non-Gaussian statistics. Yet, since optical fiber systems are only weakly nonlinear, it was commonly believed that the statistics of optical pulses is very different from the statistics encountered in strongly nonlinear systems, such as turbulence and chaotic flow, where intermittent dynamics exists. However, a recent study of pulse propagation in optical fiber systems with multiple frequency channels in the presence of delayed Raman response obtained results that stand in sharp contrast to this common belief. This study focused on the interplay between Raman induced energy exchange in pulse collisions and randomness of pulse sequences in different frequency channels. Taking into account these two effects it was shown that the pulse parameters exhibit intermittent dynamic behavior in the sense that their normalized moments grow exponentially with propagation distance. Furthermore, it was shown that this intermittent dynamic behavior has important practical consequences, by leading to relatively large values of the bit-error-rate (BER), which is the probability for an error at the output of the fiber line.

The results of the study in Ref. were based on an adiabatic perturbation procedure that neglects radiation emission effects. However, these effects can be especially important for the fiber optics system under consideration. Indeed, as we shall see below, the interplay between collision-induced energy exchange and randomness of pulse sequences can be described as an effective disorder in the linear gain/loss coefficient, and the presence of gain can lead to instability with respect to emission of continuous radiation. Therefore, it is essential to obtain an improved description of pulse dynamics in the system that includes emission of continuous waves. In this paper we take this important task and derive a perturbed stochastic nonlinear Schrödinger (NLS) equation, which takes into account both changes in pulse parameters and radiation emission effects. We employ this model to analyze the dynamics of soliton parameters in comparison with the results of the simpler description of Ref. and to draw conclusions on the possibility to observe intermittent dynamics in multichannel optical fiber communication systems. The rest of the introduction is devoted to a summary of previous research on the effects of delayed Raman response on soliton propagation in optical fibers.

The main effect of Raman scattering on a single soliton propagating in the fiber is the self frequency shift. This effect, which is caused by energy transfer from higher frequency components of the pulse to its lower frequency components, was first observed experimentally by Mitschke and Mollenauer and explained theoretically by Gordon. Following this discovery, the impact of delayed Raman response on soliton propagation in optical fibers has drawn a lot of attention. Most significantly, the influence on two-soliton collisions was studied by numerical simulations as well as by theoretical analysis. These studies revealed that the main effect of a single two-soliton collision in the presence of delayed Raman response is an energy exchange between the colliding pulses, which leads to a change of their amplitudes...
Raman induced cross talk \[13, 14, 16, 17, 18\]. The frequencies of the two solitons was also found to change as a result of the collision (Raman induced cross frequency shift) \[13, 16, 17, 18\]. Similar effects were recently studied in collisions of ultra-short soliton pulses in photonic crystal fibers \[21, 22\].

Raman induced energy exchange in pulse collisions can be beneficially employed in a variety of applications, including amplification in fiber lines \[23, 24\] and in tunable laser sources \[5, 27\]. However, it can also have negative effects that impose severe limitations on the performance of multichannel communication systems. Indeed, it is known that the Raman-induced energy exchange in a single interchannel collision is independent of the frequency difference between the channels. Consequently, the magnitude of the induced energy shifts for a given pulse grows with the square of the number of channels \[18, 26\]. Thus, in a 100-channel system, for example, these effects can be larger by a factor of \(2.5 \times 10^5\) compared with a two-channel system operating at the same bit rate per channel. Furthermore, since collisions with pulses from distant channels give the main contribution to energy shifts, a complete description of the dynamics must include interaction between pulses from all frequency channels. In contrast, effects of other nonlinear phenomena on pulse collisions are inversely proportional to some integer power of the frequency difference, and their cumulative influence can be adequately described by taking into account only a few neighboring channels \[3, 27\].

Early studies of Raman cross talk in multichannel transmission systems focused on the dependence of the induced energy shifts on the total number of channels \[28, 29\]. The combined effects of Raman cross talk and randomness of pulse sequences were also considered, and it was found that the probability distribution function (PDF) of pulse amplitudes is lognormal \[26, 30, 31, 32\]. However, these previous studies ignored several important properties of the system, which are essential for obtaining a correct dynamical model. First, all other nonlinear processes affecting pulse propagation, such as the Raman-induced self and cross frequency shifts were neglected. Second, strong coupling between amplitude dynamics and the dynamics of the other soliton parameters, such as frequency, position and phase, was not taken into account. Consequently, only the amplitude PDF was calculated, whereas a correct evaluation of system performance requires calculation of the mutual PDF of the pulse amplitude and position. Third, most studies considered only dynamic impact on performance of high frequency channels due to soliton decay, thus ignoring potential negative consequences for intermediate and low frequency channels due to large position shifts induced by relatively large amplitude values.

A more complete description of pulse propagation, which takes into account the three aforementioned factors, was developed in Refs. \[3, 33, 34\]. In Ref. \[33\] it was shown that the coupling between frequency dynamics and amplitude dynamics leads to an exponential growth of the first two normalized moments of the self and cross frequency shifts with propagation distance. A perturbed NLS equation describing the combined effects of bit pattern randomness and Raman cross talk in a two-channel system was derived in Ref. \[34\]. Numerical simulations with the latter NLS model confirmed the analytic predictions of Ref. \[33\]. Later on it was shown that for the nth normalized moments of the self and cross frequency shifts increase exponentially with both propagation distance and \(n^2\) \[6\]. These results, combined with similar results for the normalized moments of the amplitude \[33\], imply that the soliton parameters exhibit intermittent dynamics in the sense that rare but violent events associated with relatively large amplitudes and frequency shifts become important. Furthermore, it was shown that the dominant mechanism for error generation in the system at long propagation distances is related to the intermittent dynamic behavior and is due to the Raman-induced cross frequency shift \[9\]. In this process the error is generated due to large values of the frequency and position shifts induced by large amplitude values. Thus, it is very different from the two mechanisms for error generation that are usually considered in fiber optics transmission, which are due to: (1) position shift with almost constant amplitude, (2) amplitude decay with almost constant position shift. As mentioned above, the analysis in Ref. \[9\] ignored radiation emission effects, which can be important in massive multichannel transmission. In the current paper we take these effects into account and derive a perturbed stochastic NLS model for propagation in a system with \(N \geq 2\) frequency channels. We analyze the dynamics of the soliton parameters and the behavior of the BER by extensive numerical simulations with the model, and compare our results with the analytic calculations of Ref. \[9\].

The material in the rest of the paper is organized as follows. In Sec. II A, we construct a perturbed stochastic NLS model describing soliton propagation in massive multichannel optical fiber transmission systems. The dynamics of the soliton amplitude and frequency and of the BER are obtained in Sec. II B by employing a standard adiabatic perturbation procedure. In Sec. III we analyze the results of numerical simulations with the perturbed NLS model and compare them with the predictions of the adiabatic perturbation theory. Section IV is reserved for conclusions.

## II. A STOCHASTIC MODEL FOR PULSE PROPAGATION

### A. Derivation of the model

Propagation of short pulses of light through an optical fiber in the presence of delayed Raman response is described by the following perturbed NLS equation \[3\]:

\[
i \partial_t \psi + \partial_x^2 \psi + 2|\psi|^2 \psi = -\epsilon_R \partial_t |\psi|^2,
\]  

\[ \psi(0) = \psi_0(x), \]

\[ \psi(t) = \psi(x,t). \]
where \( \psi \) is proportional to the envelope of the electric field, \( z \) is propagation distance and \( t \) is time in the retarded reference frame. The term \(- \epsilon_R \psi \partial_t |\psi|^2\) accounts for the effects of delayed Raman response and \( \epsilon_R \) is the Raman coefficient [35]. When \( \epsilon_R = 0 \), the single-soliton solution of Eq. (1) in a frequency channel \( \beta \) is given by

\[
\psi_\beta(t, z) = \eta_\beta \frac{\exp(i \chi_\beta)}{\cosh(x_\beta)},
\]

where \( x_\beta = \eta_\beta (t - y_\beta - 2\beta z) \), \( \chi_\beta = \alpha_\beta + \beta(t - y_\beta) + \left( \eta_\beta^2 - \beta^2 \right) z \), and \( \eta_\beta, \alpha_\beta \) and \( y_\beta \) are the soliton amplitude, phase and position, respectively.

Consider the effects of delayed Raman response on a single collision between two solitons from different frequency channels. For simplicity, one of the two channels is chosen as the reference channel with \( \beta = 0 \) so that the frequency difference between the two channels is \( \beta \). We assume that \( \epsilon_R \ll 1 \) and \( 1/|\beta| \ll 1 \), which is the typical situation in current multichannel transmission systems [36]. In addition, we assume that the two solitons are initially well-separated from each other in the temporal domain. Under these assumptions we can employ the perturbation procedure, developed in Refs. [37, 38, 39], and applied in Ref. [34] for the case of delayed Raman response. Here we only give the outline of the calculation and refer the interested reader to Ref. [34] for details. In accordance with this perturbative approach, we look for a two-pulse solution of Eq. (1) in the form

\[
\psi_{\text{two}} = \psi_0 + \psi_\beta + \phi,
\]

where \( \psi_0 \) and \( \psi_\beta \) are single-pulse solutions of Eq. (1) with \( 0 < \epsilon_R \ll 1 \) in channels 0 and \( \beta \), respectively. The term \( \phi \) on the right hand side of Eq. (3) is a small correction to the single-soliton solutions, which is solely due to collision effects. By analogy with the ideal collision case we take \( \phi \) to be of the form

\[
\phi = \phi_0 + \phi_\beta + \ldots,
\]

where \( \phi_0 \) and \( \phi_\beta \) represent collision induced corrections in channels 0 and \( \beta \), and the ellipsis represents higher order terms in other channels. Combining Eqs. (3) and (4) we see that the total pulse in the reference channel is \( \psi_0^{\text{total}} = \psi_0 + \phi_0 \). We substitute the relations (3) and (4) together with \( \psi_0(t, z) = \Phi_0(x_0) \exp(i \chi_0), \phi_0(t, z) = \Phi_0(x_0) \exp(\chi_0), \psi_\beta(t, z) = \Phi_\beta(x_\beta) \exp(i \chi_\beta), \phi_\beta(t, z) = \Phi_\beta(x_\beta) \exp(i \chi_\beta) \) into Eq. (1). The resulting equation can be readily decomposed into an equation for the evolution of \( \Phi_0 \) and an equation for the evolution of \( \Phi_\beta \). We focus attention on \( \Phi_0 \) and remark that the calculation of \( \Phi_\beta \) is very similar. The equation for \( \Phi_0 \) is solved by integration with respect to \( z \) over the collision region. Carrying out this integration one obtains that the \( O(\epsilon_R) \) effect of the collision on the reference channel soliton is given by

\[
\Delta \Phi_0^{(1)} = \eta_\beta \text{sgn}(\beta) \epsilon_R \Phi_0(x_0),
\]

where the first subscript in \( \Delta \Phi_0^{(1)} \) stands for the channel, the second subscript indicates the combined order with respect to both \( \epsilon_R \) and \( 1/\beta \), and the superscript represents the order in \( \epsilon_R \). This \( O(\epsilon_R) \) effect corresponds to an amplitude change [13, 14, 17, 34]

\[
\Delta \eta_0 = 2\eta_0 \eta_\beta \text{sgn}(\beta) \epsilon_R,
\]

which is accompanied by emission of continuous radiation. In a similar manner, one finds that the effect of the collision in order \( \epsilon_R/\beta \) is

\[
\Delta \Phi_0^{(1)} = \frac{4i\eta_\beta \epsilon_R}{|\beta|} \partial_t \Phi_0(x_0).
\]

\[\Delta \Phi_0^{(1)}\] corresponds to a collision induced frequency shift:

\[
\Delta \beta_0 = -(\Delta \Phi_0^{(1)}(\beta)/|\beta|),
\]

which is also accompanied by emission of continuous radiation.

Let us describe propagation of a reference channel soliton in a multichannel system with an arbitrary number of channels. We employ a mean-field approximation [34] in which we assume that the amplitudes of the solitons in the other channels are constant. The random character of soliton sequences in different channels is taken into account by defining discrete random variables \( \zeta_{ij} \), which describe the occupation state of the \( j \)th time slot in the \( i \)th channel:

\[
\zeta_{ij} = 1 \text{ with probability } s \text{ if the slot is occupied, and } 0 \text{ with probability } 1 - s \text{ otherwise. It follows that the nth moment of } \zeta_{ij} \text{ satisfies: } \langle \zeta_{ij}^n \rangle = s.
\]

We also assume that the occupation states of different time slots are uncorrelated: \( \langle \zeta_{ij} \zeta_{i'j'} \rangle = s^2 \) if \( i \neq i' \) and \( j \neq j' \). We denote by \( \Delta \beta \) the frequency difference between neighboring channels and by \( T \) the time slot width. Therefore, the distance traveled by the reference channel soliton while passing two successive time slots in the nearby channels is \( \Delta z_c^{(1)} = T/(2\Delta \beta) \). The \( O(\epsilon_R) \) effects of the collisions is taken into account by introducing a new perturbation term \( S_1 \) into Eq. (1). The term \( S_1 \) is obtained by summing Eq. (5) over all collisions occurring in the interval \( \Delta z_c^{(1)} \), and dividing the result by \( \Delta z_c^{(1)} \):

\[
S_1 \equiv i \epsilon_R \Psi_0 e^{i \chi_0} \sum_{i \neq 0} \text{sgn}(\beta_i) \sum_{j = (k-1) + 1}^{k+1} \frac{\zeta_{ij}}{2} \Delta z_c^{(1)},
\]

where \( k - 1 \) and \( k \) are the indexes of the two successive time slots in the \( i = -1 \) channel, and the outside sum is from \(-N \) to \( N \). We decompose the disorder \( \zeta_{ij} \) into an average part and a fluctuating part: \( \zeta_{ij} = s + \zeta_{ij} \), where \( \langle \zeta_{ij} \rangle = 0 \), \( \langle \zeta_{ij} \zeta_{ij'} \rangle = s(1-s) \delta_{ii'} \delta_{jj'} \), and \( \delta_{ii'} \) is the Kronecker delta function. Substituting \( \zeta_{ij} = s + \zeta_{ij} \) into Eq. (9) we obtain

\[
S_1 = \frac{2i \epsilon_R \Delta \beta \psi_0}{T} \sum_{i \neq 0} \text{sgn}(\beta_i) |i| + i \epsilon_R \xi(z) \psi_0.
\]
where the continuous disorder field $\xi(z)$ is
\[
\xi(z) = \frac{1}{\Delta z^{(1)}} \sum_{i \neq 0} \sum_{j=k-1+1}^{ki} \text{sgn}(\beta_i) \tilde{\zeta}_{ij},
\] (11)

Using Eq. (11) and the properties of $\zeta_{ij}$ one can show that $\langle \xi(z) \rangle = 0$ and $\langle \xi(z)\xi(z') \rangle = D_N \delta(z-z')$, where $D_N = N(N+1)/2$, $D_2 = 2\Delta \beta_s(1-s)T^{-1}$, and $\delta(z)$ is the Dirac delta function. Notice that the first term on the right hand side of Eq. (10) is zero due to symmetry. Even if this term is not zero, it can be compensated by appropriately adjusting the gain of the amplifiers. Therefore, the $O(\epsilon_R)$ effect of the collisions is described by
\[
S_1 = i\epsilon_R \xi(z)\psi_0.
\] (12)

The $O(\epsilon_R/\beta)$ effect of the collisions is calculated in a similar manner. We first sum Eq. (7) over all collisions occurring within the interval $\Delta z^{(1)}$:
\[
\tilde{S}_2 \equiv -c_1 \partial_t \Psi_0 - 4\epsilon_R \partial_t \Psi_0 \sum_{i \neq 0} \sum_{j=k-1+1}^{ki} \tilde{\zeta}_{ij},
\] (13)

where $c_1 = (16N\epsilon_R^8)/T$. The second term on the right hand side of Eq. (13) can be estimated as $-8[D_2 H_N/(T\Delta \beta)]^{1/2}\epsilon_R \partial_t \Psi_0$, where $H_N = \sum_{j=1}^{N} 1/j$. Consequently, for a typical multichannel system the coefficient in front of $\epsilon_R \partial_t \Psi_0$ in this term is of order 1 or smaller, whereas for the first term this coefficient is of order $N$. We therefore neglect the second term on the right hand side of Eq. (13), and set $\tilde{S}_2 = -c_1 \partial_t \Psi_0$. Using the fact that for a weakly perturbed soliton $e^{i\Psi_0} \partial_t \Psi_0 = \partial_t \psi_0 - i\beta_0 \psi_0$ we arrive at
\[
S_2 \equiv e^{i\Psi_0} \tilde{S}_2 = -c_1 \partial_t \psi_0 + ic_1 \beta_0 \psi_0,
\] (14)

where $\beta_0$ is the frequency of the perturbed reference channel soliton. Substituting $S_1$ and $S_2$ into Eq. (11) and replacing $\psi_0$ with $\psi$ we obtain
\[
i\partial_t \psi + \partial_t^2 \psi + 2|\psi|^2 \psi = -\epsilon_R \psi \partial_t |\psi|^2
+ic_R \xi(z)\psi - c_1 \partial_t \psi + ic_1 \beta_0 \psi,
\] (15)

which is the stochastic model describing propagation of the reference channel soliton in the fiber under many collisions.

B. Statistics of soliton parameters and BER calculation

The evolution of the parameters of the reference channel soliton with propagation distance can be obtained by employing the standard adiabatic perturbation theory [40, 41]. Employing this perturbation procedure we obtain the following equations for the soliton amplitude and frequency:
\[
\frac{d\eta_0}{dz} = 2\epsilon_R \xi(z)\eta_0(z),
\] (16)

and
\[
\frac{d\beta_0}{dz} = -\frac{8}{15} \epsilon_R \eta_0^4(z) - \frac{2}{3} c_1 \eta_0^2(z).
\] (17)

Notice that the right hand side of Eq. (16) is contributed solely by the second term on the right hand side of Eq. (15), i.e., the term describing the Raman cross talk effects. The first and second terms on the right hand side of Eq. (17) describe the Raman induced self- and cross-frequency shifts, and are contributed by the first and third right hand side of Eq. (16), respectively.

Integrating Eq. (16) over $z$ we obtain
\[
\eta_0(z) = \eta_0(0) \exp \left[ \frac{2\epsilon_R x(z)}{\eta_0(0)} \right],
\] (18)

where $x(z) = \int_0^z \xi(z') \, dz'$ and $\eta_0(0)$ is the initial amplitude. According to the central limit theorem, the PDF of $x(z)$ approaches a Gaussian PDF with $\langle x(z) \rangle = 0$ and $\langle x^2(z) \rangle = D_N z$. As a result, the PDF of the soliton amplitude approaches a lognormal PDF:
\[
F(\eta_0) = \left( 8 \pi D_N \epsilon_R z \right)^{-1/2} \exp \left\{ -\frac{\ln^2 [\eta_0/\eta_0(0)]}{8 D_N \epsilon_R^2 z} \right\}.
\] (19)

The lognormal distribution is very different from the Gaussian distribution, and this difference is significant already in the main body of the distribution [34]. Moreover, the normalized moments of the lognormal PDF grow exponentially with propagation distance, from which it follows that the soliton amplitude exhibits intermittent dynamic behavior [34].

The dynamic evolution of the soliton frequency is given by
\[
\beta_0(z) = \beta_0^{(s)}(z) + \beta_0^{(c)}(z),
\] (20)

where
\[
\beta_0^{(s)}(z) = -\frac{8}{15} \epsilon_R \int_0^z dz' \eta_0^4(z'),
\] (21)

is the self frequency shift and
\[
\beta_0^{(c)}(z) = -\frac{32 N \epsilon_R^8}{3T} \int_0^z dz' \eta_0^2(z')
\] (22)

is the cross frequency shift. The $n$th moments of $\beta_0^{(s)}$ and $\beta_0^{(c)}$ can be calculated from [3]
\[
\langle \beta_0^{(s)}(z) \rangle = \left[ -\frac{8}{15} \epsilon_R \eta_0^4(0) \right]^n n!
\times \prod_{m=1}^n \int_0^{z_{m-1}} dz_m \exp \left[ 32 D_N \epsilon_R^2 (2m-1) z_m \right],
\] (23)

and
\[
\langle \beta_0^{(c)}(z) \rangle = \left[ -\frac{2}{3} c_1 \eta_0^2(0) \right]^n n!
\times \prod_{m=1}^n \int_0^{z_{m-1}} dz_m \exp \left[ 8 D_N \epsilon_R^2 (2m-1) z_m \right],
\] (24)
where \( z_0 = z \). By carrying out the integration in Eqs. (24) and (25) one can show that \( \langle \beta_0^{(s)c} \rangle (z) \) and \( \langle \beta_0^{(c)c} \rangle (z) \) are given by sums over exponential terms of the form

\[
K_m \exp \left[ a(s,c) m^2 D N \xi_0^2 R \right],
\]

where \( a(s) = 32, a(c) = 8, 0 \leq m \leq n \), and the \( K_m \) are constants. Furthermore, the leading contributions to the normalized moments \( \langle \beta_0^{(s)c} \rangle (z) / \langle \beta_0^{(s)c} \rangle ^n(z) \) and \( \langle \beta_0^{(c)c} \rangle (z) / \langle \beta_0^{(c)c} \rangle ^n(z) \) are exponentially increasing with both \( z \) and \( n^2 \). As we shall see in the next Section, the normalized fourth moments of \( \beta_0^{(s)} \), \( \beta_0^{(c)} \) and \( \beta_0 \) increase much faster with increasing propagation distance compared with the normalized second and third moments, which is a consequence of the intermittent nature of the dynamics.

In order to evaluate the system’s BER we need to consider the main dynamical mechanisms leading to error generation. One mechanism, which has been widely studied in relation with Raman cross talk, is due to pulse decay induced by loss of energy in collisions. This mechanism is associated with the small-\( \eta \) tail of the amplitude PDF. Another mechanism, which has only recently been studied in relation with Raman cross talk, is due to the interplay between frequency (and position) dynamics and amplitude dynamics. In this case, the error is generated due to large values of the position shift, which are associated with large frequency shifts, and induced by relatively large values of the soliton amplitude. Notice that the lognormal statistics of the soliton amplitude leads to further enhancement of the BER contribution from the latter mechanism, since the large-\( \eta \) tail of the lognormal PDF lies above the corresponding tail of the Gaussian PDF. We are therefore interested in the soliton position shift, which is given by

\[
y_0(z) = y_0^{(s)}(z) + y_0^{(c)}(z),
\]

where

\[
y_0^{(s)}(z) = -\frac{16\epsilon_R}{15} \int_0^z dz' \int_0^z dz'' \eta_0^4(z''),
\]

and

\[
y_0^{(c)}(z) = -\frac{64N\epsilon_R s}{3T} \int_0^z dz' \int_0^z dz'' \eta_0^2(z'')
\]

are the contributions from the self and cross frequency shifts, respectively. The position shift with a fixed amplitude \( \eta_0(z) = \eta_0(0) = 1 \) is \( y_0(z) = y_0^{(s)}(z) + y_0^{(c)}(z), \) where \( y_0^{(s)}(z) = -8\epsilon_R z^2 \)/15 and \( y_0^{(c)}(z) = -(32N\epsilon_R s z^2)/(3T) \). The relative position shift is \( \Delta y_0(z) = \Delta y_0^{(s)}(z) + \Delta y_0^{(c)}(z), \) where \( \Delta y_0^{(s)}(z) = y_0^{(s)}(z) - y_0^{(s)}(0) \) and \( \Delta y_0^{(c)}(z) = y_0^{(c)}(z) - y_0^{(c)}(0). \) We assume that \( \eta_0 \) can be compensated by employing filters. Therefore, the energy measured by the detector at a distance \( z \) is

\[
I(\eta_0, \Delta y_0) = \eta_0^2 \int_{-T/2}^{T/2} dt \cos^2[\eta_0(t - \Delta y_0)].
\]

An occupied time slot is considered to be in error, if \( I(\eta_0, \Delta y_0) \leq I(z = 0)/2 \approx 1 \). We estimate the BER by numerically integrating Eqs. (24) and (25) coupled to Eq. (15) for different realizations of the disorder \( \xi(z) \) and calculating the fraction of errored occupied time slots. The \( z \)-dependence of the BER obtained by this calculation is described in Sec. III.

### III. NUMERICAL SIMULATIONS

In the previous Section we calculated the statistics of the soliton parameters and the BER by employing the adiabatic perturbation theory and neglecting effects associated with emission of continuous radiation. We note that the latter effects can be particularly important for the system described by Eq. (15). Indeed, the second term on the right hand side of this equation has the form of disorder in the linear gain/loss coefficient. Such term can lead to instability with respect to emission of continuous radiation, which is of second order in \( c \epsilon_R \). It is therefore important to compare the results obtained in the previous Section by the reduced adiabatic method with results of numerical simulations with the more complete model, described by Eq. (15).

Notice that the fourth term on the right hand side of Eq. (15) includes \( \beta_0 \). Since both \( \beta_0 \) and \( c_1 \) are of order \( \epsilon_R \) this term is of order \( \epsilon_R^2 \), whereas the other perturbation terms in the equation are of order \( \epsilon_R \). Moreover, since \( \beta_0 \) is a \( z \)-dependent random variable it is computationally complicated to solve Eq. (15) in its exact form. To overcome this problem, we replace \( \beta_0 \) in Eq. (15) with its value for the case where the amplitude is fixed and equal to 1: \( \tilde{\beta}_0(z) = -\frac{1}{3}(2N\epsilon_R s z)/(3T) - (8\epsilon_R z)/15. \) Thus, the perturbed NLS which we solve numerically is

\[
i\frac{\partial^2 \psi}{\partial t^2} + \frac{\partial^4 \psi}{\partial z^4} + 2|\psi|^2 \psi = -\epsilon_R \psi \frac{\partial \psi}{\partial t} + i\epsilon_R \xi(z) \psi - c_1 \frac{\partial \psi}{\partial t} + i c_2 \tilde{\beta}_0(z) \psi.
\]

The initial condition is taken in the form of an ideal soliton: \( \psi(t, z = 0) = \cos \frac{1}{2}(t), \) with \( \eta_0(0) = 1, \beta_0(0) = 0, \) \( y_0(0) = 0, \) and \( \alpha_0(0) = 0. \)

We perform Monte Carlo simulations with Eq. (24) with about \( 5 \times 10^4 \) disorder realizations. The equation is integrated by employing the split-step method with periodic boundary conditions. Numerical errors resulting from radiation emission and the use of periodic boundary conditions are overcome by applying artificial damping at the vicinity of the boundaries of the computational domain. The size of the domain is taken to be \( -100 \leq t \leq 100 \) so that the absorbing layers do not affect the dynamics of the soliton pulses. The \( t \)-step and \( z \)-step are taken as \( \Delta t = 0.048 \) and \( \Delta z = 0.001 \), respectively.

We focus attention on a transmission system with 101 channels operating at 10 Gbits/s per channel. It should be emphasized that state-of-the-art experiments with dispersion-managed solitons demonstrated multichannel transmission with 109 channels at 10 Gbits/s per channel over a distance of \( 2 \times 10^4 \) km [42]. Several other
experiments achieved total bit-rate capacities exceeding 1Tbits/s for shorter propagation distances \[43, 44, 45\]. We use the following set of parameters, which is similar to the one used in multichannel transmission experiments with conventional solitons \[36\]. Assuming that \( T = 5 \), \( \Delta \beta = 10 \), \( s = 1/2 \) and \( \eta_s(0) = 1 \) for all channels, the pulse width is 20 ps, \( \epsilon_R = 3 \times 10^{-4} \), the channel spacing is 75 GHz, and \( D_z = 1 \). Taking \( \beta_z = -1 \text{ps}^2/\text{km} \), the soliton-peak-power is \( P_0 = 1.25 \text{mW} \). For these values the width of the lognormal PDF in Eq. \[39\], which represents the strength of disorder effects, is \( 8D_N \sigma_R^2 z = 1.8 \times 10^{-3}z \) for the reference channel. For \( z = 25 \), corresponding to transmission over \( 2 \times 10^4 \text{km} \), \( 8D_N \sigma_R^2 z = 0.046 \).

The \( z \)-dependences of the \( n = 2, 3, 4 \) normalized moments of \( \beta_0^{(s)} \), \( \beta_0^{(c)} \), and \( \beta_0 \) as obtained by numerical solution of the perturbed NLS are shown in Fig. 1 together with the results of the adiabatic perturbation theory. The numerical simulation results for \( \beta_0^{(s)} \) and \( \beta_0^{(c)} \) were obtained by solving the reduced models

\[
-i\partial_z \psi + \partial^2_t \psi + 2|\psi|^2 \psi = -\epsilon_R \partial_t |\psi|^2 + i\epsilon_R \xi(z) \psi, \tag{30}
\]

and

\[
-i\partial_z \psi + \partial^2_t \psi + 2|\psi|^2 \psi = i\epsilon_R \xi(z) \psi - c_1 \partial_t \psi + i c_1 \tilde{\beta}_0(z) \psi \tag{31}
\]

with \( \tilde{\beta}_0(z) = -(32N \epsilon_R z)/(3T) \), respectively. The results obtained by numerical solution of the perturbed NLS equation are in good agreement with those obtained by the adiabatic perturbation theory. Moreover, one can see that the fourth moments of \( \beta_0^{(s)} \), \( \beta_0^{(c)} \), and \( \beta_0 \) increase much faster with increasing \( z \) compared with the second and third moments, in accordance with the intermittent nature of the dynamics. In addition, the normalized moments of \( \beta_0^{(s)} \) grow faster than those of \( \beta_0^{(c)} \). This can be explained by noting that the rate of change of \( \beta_0^{(s)} \) is proportional to \( \eta_s^4 \), whereas \( d\beta_0^{(c)}/dz \) is proportional to \( \eta_0^2 \). Notice, however, that the values of the normalized moments of the total frequency shift \( \beta_0 \) are very close to those of \( \beta_0^{(c)} \). This is due to the fact that for the system described above \( \beta_0^{(c)} \) is typically much larger than \( \beta_0^{(s)} \).

The BER of the reference channel is calculated by the procedure described in Sec. II B. That is, we calculate the measured intensity using Eq. \[28\], and declare an occupied time slot to be in error, if \( I(\eta_0, \Delta \eta_0) \leq I(z = 0)/2 \approx 1 \). The \( z \)-dependence of the BER obtained by numerical integration of Eq. \[29\] is shown in Fig. 2 together with the result obtained by employing the adiabatic perturbation procedure. The agreement between the perturbed NLS simulations and the corresponding adiabatic theory calculations is good. Furthermore, it is seen that the BER retains relatively large values, which range from about \( 3 \times 10^{-5} \) for \( z = 16 \) (\( X = 1.28 \times 10^4 \text{ km} \)) to about \( 10^{-1} \) at \( z = 25.0 \) (\( X = 2 \times 10^4 \text{ km} \)). We remark that the BER values obtained by integrating Eq. \[31\], which takes into account only \( \eta_0^{(c)} \), are very close to the ones obtained by solving Eq. \[29\], which takes into account both \( \eta_0^{(s)} \) and \( \eta_0^{(c)} \). In fact, since the difference between the two BER curves is indistinguishable on the scale of Fig. 2, we choose to omit the result obtained with Eq. \[31\]. The fact that the two models [Eq. \[29\] and Eq. \[31\]] give such close BER values is explained by noting that the cross frequency shift is typically much

---

**FIG. 1:** Normalized moments of the reference channel soliton’s cross frequency shift (a), self frequency shift (b), and total frequency shift (c) vs propagation distance \( z \) for a multichannel system with 101 channels at 10 Gbits/s per channel. The solid, dashed-dotted, and dashed lines correspond to the \( n = 2, 3, 4 \) normalized moments obtained by the adiabatic perturbation method, using Eqs. \[22\] and \[24\] in (a), Eqs. \[22\] and \[24\] in (b), and Eqs. \[22\] and \[24\] in (c). The circles, squares, and crosses represent the \( n = 2, 3, 4 \) normalized moments obtained by numerical integration of Eq. \[31\] in (a), Eq. \[31\] in (b), and Eq. \[31\] in (c).
larger than the self frequency shift for the multichannel system considered here.

As explained in Section II and in Ref. [9], the two main mechanisms for error generation in the multichannel system are: (1) pulse decay, (2) large position shifts. While the first mechanism is associated with small pulse amplitudes, the second one is predominantly due to large amplitudes. Hence, in order to better understand the roles of these two error-generating mechanisms one has to study the mutual PDF \( G(\eta_0, \Delta y_0) \). Figure 3 shows \( G(\eta_0, \Delta y_0) \) for the reference channel soliton at the final propagation distance \( z = 25 \). The result obtained by numerical solution of Eq. (29) (Fig. 3(a)) is in good agreement with the prediction of the adiabatic perturbation theory (Fig. 3(b)). Moreover, the mutual distribution function is strongly asymmetric about the \( \Delta y_0 = 0 \) and \( \eta_0 = 1 \) axes. This asymmetry is a direct consequence of the strong coupling between position dynamics and amplitude dynamics, as can be seen from Eqs. (26) and (27). We emphasize that this behavior is very different from the one observed for soliton propagation in single-channel systems in the presence of amplifier noise, where the mutual PDF is approximately symmetric with respect to both \( \Delta y_0 = 0 \) and \( \eta_0 = 1 \) [6, 8]. We also note that the mutual PDF shown in Fig. 3 is skewed toward larger \( \eta_0 \) values, which can be explained by the skewed character of the lognormal distribution \( F(\eta_0) \).

IV. CONCLUSIONS

We investigated propagation of optical pulses in massive multichannel optical fiber communication systems, taking into account the effects of delayed Raman response and bit pattern randomness. We derived a mean-field

![FIG. 3: The mutual PDF \( G(\eta_0, \Delta y_0) \) for the reference channel soliton at \( z = 25 \) as obtained by numerical integration of Eq. (29) (a), and as predicted by the adiabatic perturbation method (b).](image)
dispersion-managed (DM) solitons are very similar to the effects in the conventional soliton case [18]. Therefore, we expect that similar results would hold for DM multichannel transmission systems as well. A different type of nonlinearity that can lead to similar dynamics is due to nonlinear loss/gain. In this case pulse propagation is described by a perturbed NLS equation, in which the \(-\epsilon R\partial_t |\psi|^2\) term is replaced by \(\mp \epsilon_c |\psi|^2 \psi\), where \(\epsilon_c\) is the cubic nonlinear loss/gain coefficient. It can be shown that the main effect of a fast collision in the presence of nonlinear loss/gain is a change in the soliton amplitude, which is given by an equation of the form (\(\psi\) with \(\text{sgn}(\beta)\epsilon_R\) replaced by \(\mp 2 \epsilon_c |\beta|\)). If additional perturbations that affect the soliton frequency and position exist, the dynamics of the frequency or position will usually be coupled to the amplitude dynamics in a manner similar to the one described in Section II. Consequently, our results should also be applicable for propagation of NLS solitons in systems with nonlinear loss or gain.
