Abstract
We use a simple dynamical model and explore coherent dynamics of wavepackets in complex networks of optical fibers. We start from a symmetric lattice and through the application of a Monte–Carlo criterion we introduce structural disorder and deform the lattice into a small-world network regime. We investigate in the latter both structural (correlation length) as well as dynamical (diffusion exponent) properties and find that both exhibit a rapid crossover from the ordered to the fully random regime. For a critical value of the structural disorder parameter $\rho \approx 0.25$ transport changes from ballistic to sub-diffusive due to the creation strongly connected local clusters and channels of preferential transport in the small world regime.

Keywords: small-world networks, structural disorder, optical fibers, self-trapping, sub-diffusion

(Some figures may appear in colour only in the online journal)

1. Introduction

Small world networks have attracted great interest in the last decades due to the very broad applicability to real-life problems ranging from social networks, to physics, chemistry and biology [1–6]. Some of the unique properties that arise in the small-world regime are robustness (high clustering coefficient), combined with efficient transport properties (low average path length) [7–9]. Quantum dynamics simulations on scale free networks indicate a phase transition in the transport properties as one approaches the thermodynamic limit [9–11]. Even though small-world networks have been extensively studied focusing on diffusive properties and using a classical statistical description, wave-like propagation properties have not attracted considerable attention yet. In the present contribution, the small-world concept is applied to an optical or equivalently to a quantum mechanical system. In particular we model an optical fiber lattice that exhibits small-world network topology. The transport properties of this network are investigated and compared with those of an ordered as well as a uniformly random network. The dynamics of the system are governed by the amount of structural disorder present in the network.

Experimental investigations of disordered optical lattices indicate that a small amount of disorder is sufficient to lead to Anderson localization [12–16]. In this case the excited wavepacket does not disperse but instead remains partially localized due to the dielectric index disorder in the medium. A different source for localization is nonlinearity: when the interaction of the wavepacket with the medium is highly nonlinear it can lead to self-trapping [17, 18]. For example, when a laser pulse interacts with a highly responsive medium, it can lead to self focusing and soliton formation [19–21]. Self-trapping is known to occur abruptly at a threshold which depends on the system properties such as size and geometry [22–26].

In the present article we investigate primarily the impact of structural disorder on the wavepacket dynamics on a 2D lattice. The specific form of disorder used leads to the formation of a
small world network lattice that is parametrized through a randomness parameter. Additionally, we observe the effects that nonlinearity may induce, viz. that nonlinearity rapidly leads to self-trapping, while structural disorder acts like a barrier creating channels in which transport is favoured, leading to anomalous diffusion. Previous investigations on optical random media indicate that nonlinearity can emerge from structural disorder in the form of branched wave patterns [27]. In the current investigation we essentially disentangle these two parameters and explore the possibility of tuning independently localization due to structural disorder and due to self-trapping.

2. The small-world lattice

The physical system we are addressing consists of a lattice or network of optical fibers that permits light propagation along the fibers plus some interfiber interaction due to evanescent coupling. In figure 1 we show an ordered square lattice, where the points correspond to the optical fibers position on the x-y plane. The fibers extend along the z direction, which in a paraxial approximation corresponds to time [28]. Initially, one of the fibers is excited and by measuring the intensity profile of the lattice for different cuts along the z-axis, one acquires the dynamics of the excited wavepacket on the lattice.

Figure 1. (a) The 2D lattice of the optical fiber position for different values of the structural disorder parameter $\rho$. The corresponding network configurations in the (b) spring and (c) circular embedding.
structural disorder is sufficient for the emergence of the small-world properties.

We can construct a network out of a 2D lattice by assigning the fibers as the network nodes while the interaction between the optical fibers are the edges. This treatment yields a weighted network [29], where the weight of the edges depends on the distance between the points on the 2D plane in the following way:

\[ w_{ij} = A \cdot e^{-\phi_{ij}}, \]

where \( w_{ij} \) is the weight that links any two fibers labeled \( i \) and \( j \) respectively, \( \phi_{ij} \) is the distance between these fibers, \( \phi_0 \) a characteristic length scale and \( A \) is weight amplitude. This form of edges models reasonably well the fiber crosstalk, i.e. the tunneling probability between fibers. In figure 1(b) we show the networks that arise from the 2D lattices for the cases where \( \rho = 0, \rho = 0.1 \) and \( \rho = 1 \). To facilitate comparison between the three networks the edges are shown only above a certain weight (0.01%). The algorithm used to optimize the network topology is the spring embedding, which assumes a ball-string relationship between the nodes of the system.

In the ordered case (\( \rho = 0 \)) the network is a 2D manifold corresponding precisely to the 2D lattice. For a small amount of structural disorder (\( \rho = 0.1 \)) a few nodes have been repositioned, creating holes on the one hand and patches of increased density on the other. This treatment leads to the formation of local clusters, making some of the nodes of the network highly connected and others more disconnected. This is the key feature of the network, which as we will see has a significant impact on the dynamics. In the fully random case (\( \rho = 1 \)) the network has been essentially fractured to smaller fractions, which are very weakly connected among them. The exact value that the network passes to the fractured regime relates to the site and bond percolation threshold of the network [30, 31].

An more common network graphical representation is the circular embedding, shown in figure 1(c). The nodes are placed on a circle and the corresponding edges are drawn between them. Then instead of repositioning the nodes like in the real 2D lattice and in the spring embedding, they are kept in fixed positions and instead the edges are redirected. From this point of view \( \rho \) can also be understood as the network rewiring probability. It has been shown that by following this procedure small-world properties arise at very small values of \( \rho \) [7]. Using this approach we can analyze the disordered 2D lattice as a weighted network. This method allows us to make a direct connection between the lattice transport properties and the network topology and simplify the simulations by mapping the 2D lattice plane to a reduced adjacency matrix.

To quantify the structural local change of the lattice as a function of increasing structural disorder, we calculate the correlation length for different \( \rho \)'s. This can be achieved by calculating the standard deviation of the correlation function of the disordered network, which is normalized with respect to the ordered lattice. In order to have a statistically good ensemble, we make 50 realizations for 500 different steps of the disorder parameter \( \rho \). The resulting correlation length decays rapidly as a function of the disorder parameter, as can be seen from figure 2. To extract consistently a single value for the correlation length decay, we fit with a single exponential function (red curve) yielding \( \rho_t = 0.28 \). As we discuss also below this value signals the regime between ordered and random network; this feature emerges in both the structural and dynamical aspects of the system. The corresponding offset of 0.26, observed for larger values of the disorder parameter is due to the finite system size (400 points).

3. Dynamics

To simulate the dynamics of the excited wavepacket on the 2D lattice use the discrete nonlinear Schrödinger equation (DNLS) [22, 24, 25, 32]:

\[ i \frac{d\psi_i}{dt} = V_{i,n}\psi_n - \chi |\psi_i|^2 \psi_i, \]

where \( V \) is the network adjacency matrix, which contains the weights between the vertices. The second term introduces anharmonicity with the nonlinearity parameter \( \chi \). The DNLS equation is an ideal choice to depict the evolution, because it can describe realistically the tunneling of a wavepacket through optic fibers and allows one to explore the influence of nonlinearity on the dynamics. The resulting dynamics are displayed on figure 3, where the color values indicate the amplitude of wavepacket between 0 (blue) and 1 (white). Initially the wavepacket is placed in the central lattice site; in an experiment, this initial condition corresponds to the excitation of a single fiber. In the vertical sections we show selections of snapshots from the evolution of the wavepacket, while on the right hand side we portray the wavepacket mean–square–displacement (MDS) as a function of time. In the ordered lattice with no nonlinearity (figure 3(a)), where \( \rho = 0 \) and \( \chi = 0 \) the wavepacket spreads ballistically. This is quantified through the function \( f(t) = Dt^\alpha \) where \( D \) is the diffusion coefficient and \( \alpha \) the diffusion exponent. In the ballistic case, the fit yields \( \alpha = 2 \) (blue line). We note that
these results correspond to finite system behaviour that stop every time light reached the edge fibers due to diffraction.

We also examine the influence of nonlinearity in the ordered lattice (figure 3(b)). As expected from previous investigations [22, 24–26], self-trapping of the wavepacket occurs abruptly above a certain value of the nonlinearity parameter \( \chi \). This is characteristically depicted on the dynamics, as can be seen from the snapshots for \( \chi = 10 \). Even though the wavepacket initially spreads \( (t = 1) \), due to the intense self-interaction introduced by the nonlinear term it is then trapped at the initial site \( (t = 3) \). Additionally, a small fraction of the wavepacket spreads through the rest of the lattice. The mean–square–displacement of the wavepacket is shown for different values of the nonlinear parameter \( \chi \) on the right–hand panel.

One can see that the wavepacket exhibits ballistic behaviour for smaller values of the nonlinearity parameter, whereas a rapid change of behaviour occurs for greater \( \chi \)’s. This feature becomes clear when plotting the fitted diffusion exponents \( \alpha \) as a function of the nonlinearity parameter \( \chi \) (figure 4). When increasing nonlinearity, the system changes from ballistic behaviour to partial delocalization and finally to self trapping. A sigmoidal function fit (stretched exponential —red line) yields the characteristic value of \( \chi_c \), which signifies the passing to the self-trapped regime. This feature has been studied extensively in previous investigations, where it was shown that the value \( \chi_c \) critically depends on the system size and geometry [22–26]. Here, we see that this property also holds for the 2D lattice and additionally discover that a small fraction of the wavepacket is not trapped. In the simulations we use open boundary conditions; we verified that implementing periodic boundary conditions does not significantly alter our results and simply shifts the critical nonlinearity value \( \chi_c \), as shown in 1D networks [22], since we essentially limit our studies on the early wavepacket dynamics, where the probability amplitude is nearly zero near the boundaries. Furthermore, similar effects are observed for the system size: self-trapping is known to depend critically on system size [22], which again can shift in our system the critical nonlinearity \( \chi_c \) in an analogous way to the 1D system.

An alternative way to localize the excitation is by incorporating disorder, which has been previously observed theoretically and experimentally in optical lattices [12–16]. By using the procedure described in figure 1, structural disorder is introduced to the system and the dynamics is examined in the regime in between an ordered lattice and a completely random one. In figure 3(c) we show snapshots from the dynamics in a lattice with disorder parameter \( \rho = 0.3 \). Naturally, structural disorder acts like a barrier, slowing down dramatically all dynamics while creating new channels of transport as can be seen clearly in the latter snapshots \( (t = 10^3) \). As a result the diffusion exponent decreases, in this case to \( \alpha \approx 1.14 \) (the traces shown in the disordered cases are averaged over 50 different lattices). For a completely random lattice (figure 3(d) —\( \rho = 1 \)) we observe that the wavepacket remains localized within the observed timescales and exhibits sub-diffusion with corresponding diffusion exponent \( \alpha = 0.29 \). This behaviour is quantified in figure 5, where is shown the diffusion exponent \( \alpha \) as a function of the disorder parameter \( \rho \). We consider this as the main result of the paper: the system passes from normal diffusion to sub-diffusion with increasing structural disorder, even though nonlinearity is absent. A characteristic value of \( \rho = 0.22 \) is extracted from the fit (stretched exponential—red line), which signifies the passage to sub-diffusive behaviour. The residual offset \( (\alpha_0 = 0.23) \) is due to trapping of the wavepacket in the initial position, which exhibits Anderson-like localization. The transition to sub-diffusion signifies the passage from an ordered network to a small-world regime. Finally including a combination of both nonlinearity and structural disorder leads to very strong localization \( (\alpha \approx 0.18) \) as shown in figure 4(e) for the corresponding critical values \( \rho \) and \( \chi_c \).

4. Conclusions

In the present paper is discussed a simple model describing the dynamics of a wavepacket in an 2D lattice, in the presence of structural disorder and nonlinearity. In an experiment, the 2D lattice can refer to the tips of an optic fiber network; the dynamics examined refer to the excitation of one fiber and recording the intensity of the surrounding ones.

In an ordered lattice with no nonlinearity, we observe, as expected, that the system exhibits ballistic behaviour. Nonlinearity is introduced through the DNLS equation, which lead to self-trapping for values larger than \( \chi_c = 7.5 \). On the other hand, structural disorder is introduced to the system by mapping the 2D lattice to a network, and repositioning the nodes with a Monte–Carlo criterion and probability \( \rho \). As structural disorder increases, we observe a transition with regard both the structural and dynamical properties of the system at about \( \rho = 0.25 \). The correlation length decreases rapidly \( (\rho_1 = 0.28) \) and a passage is noted from normal
Figure 4. The dynamics of the wavepacket and the corresponding mean-square-displacement (MSD) as a function of time. (a) The linear case in the ordered lattice. Finally the combination of nonlinearity and disorder leads to strong localization (e).
as a function of the disorder parameter $\rho$. For small $\rho$'s the system exhibits normal diffusion, whereas for larger ones ($\rho > 0.22$) it switches to sub-diffusion. 

Figure 5. The diffusion exponent $\alpha$ as a function of the disorder parameter $\rho$. For small $\rho$'s the system exhibits normal diffusion, whereas for larger ones ($\rho > 0.22$) it switches to sub-diffusion ($\rho_c=0.22$). From the network analysis this result is understood as a signature of the small-world regime: strongly connected local clusters are created, which are weakly connected among them, and therefore channels of preferential transport arise, leading to sub-diffusion. 

Numerical results indicate that the combination of structural disorder with nonlinearity leads to almost complete localization of the wavepacket, for values bellow the self-trapping threshold ($\chi_s = 7.5$), which is in agreement with previous investigations [25, 26]. It would be very illuminating to perform the experiments discussed here and actually see whether one can control diffusion through the lattice geometry (disorder) and laser intensity (nonlinearity), and probe experimentally the small-world regime. Additionally, it would be interesting to extend the same line of investigation to different complex network topologies, such as the apollonian networks, in which is known that one can observe quantum phase transitions of light [9–11].
