INTRODUCTION

*Trichophyton interdigitale* is a major pathogen that causes dermatophytosis, such as tinea pedis and tinea unguium. The gold standard for the diagnosis or evaluation of the therapeutic outcome of dermatophytosis is a direct KOH examination and fungal culture. However, difficulties are associated with its identification due to morphological similarities, variabilities and polymorphisms in dermatophytes. Therefore, in addition to these conventional diagnostic methods, molecular biological techniques using PCR for the diagnosis of dermatophytosis have been developed to detect and identify the fungal strain from clinical isolates and specimens affected by dermatophytes. Among them, internal transcribed spacer (ITS) region, located between the 18S and the 28S ribosomal DNA (rDNA), targeted PCR method, such as PCR-restriction

**Summary**

**Background:** Ribosomal DNA (rDNA) reportedly has multiple copies in the fungal genome. The internal transcribed spacer (ITS) region in rDNA is useful for investigating relationships between close taxonomic relatives. Thus, ITS has been widely used as a target gene in medical mycology for the detection of pathogenic fungi and identification of fungal species. However, the rDNA copy number in a genome of *Trichophyton interdigitale*, the pathogen causing dermatophytosis, currently remains unknown.

**Objective:** Clarification of the rDNA copy number in a genome of *T. interdigitale*.

**Methods:** rDNA copy numbers in 64 clinical isolates of *T. interdigitale* were examined using quantitative real-time PCR (qPCR) with the absolute quantitative method targeting TruMDR2, a single-copy control gene and the ITS region in rDNA.

**Results:** The copy numbers of the rDNA subunit varied among the 64 strains tested, from 24 to 116 copies per genome. The average rDNA copy number ± standard deviation was 59 ± 16. No correlations were observed between the rDNA copy number and colony colour, colony morphology or molecular type of the non-transcribed spacer region in rDNA. Experiments on rDNA copy numbers obtained from independent colonies of each strain in single-spore cultures revealed that the copy number was homogeneous within each strain.

**Conclusion:** This is the first study to estimate copy numbers of the rDNA subunit in a genome of *T. interdigitale*. The rDNA copy number of *T. interdigitale* varied among the strains tested and was homogeneous within each strain.

**KEYWORDS**

dermatophytes, quantitative real-time PCR, ribosomal DNA, *Trichophyton interdigitale*
fragment length polymorphism (RFLP),⁶–⁸ have been widely applied to the identification of dermatophytes species. Because 18S and 28S rDNA are useful PCR targets because of their sequence conservation in dermatophytes, which has allowed for the use of universal primers that enable the amplification of targets from unknown dermatophyte species.⁹ A second advantage of targeting rDNA is that the DNA sequence of the ITS region considerably varies between fungal species and exhibits adequate variability for differentiating between closely related dermatophyte species.¹⁰–¹⁴ Furthermore, a genome is known to have multiple copies of rDNA. Thus, the detection of rDNA is more advantageous than other single-copy genes.

rDNA repeats in the fungal genome were previously reported to be between 28 and 118 using six fungal species,¹⁵ and between 14 and 1442 using 91 species.¹⁶ These data contribute to estimations of the amount of pathogenic fungi in affected specimens. However, the copy number in a genome (copy number) of T. interdigitale and whether all strains have the same number of rDNA subunits currently remain unclear. According to previous studies on other fungi, the rDNA copy number varied among strains and ranged between 56 and 225 copies per genome in four strains of Leptosphaeria maculans,¹⁷ between 54 and 511 copies per genome in 36 strains of Saccharomyces cerevisiae;¹⁸ and between 38 and 91 copies per genome in eight strains of Aspergillus fumigatus.¹⁹ Furthermore, the rDNA copy number of A. fumigatus remained stable under various environmental conditions.¹⁹

In the present study, we investigated rDNA copy numbers in 64 isolates of T. interdigitale by qPCR. The homogeneity of rDNA copy numbers in each strain of T. interdigitale was assessed by sampling genomic DNA from independent colonies in single-spore cultures.

2 | MATERIALS AND METHODS

2.1 | Ethics statement

The authors confirm that the ethical policies of the journal, as noted on the journal’s author guidelines page, have been adhered to. No ethical approval was required as the research in this article related to micro-organisms.

2.2 | Fungal strains

All 64 clinical isolates of T. interdigitale were obtained from the culture collection of Kanazawa Medical University (KMU). They were identified by colony morphology, a PCR-RFLP analysis² and the sequence analysis of the ITS region in rDNA. The ITS sequence was determined using the primer of ITS4 and ITS5,² BigDye™ Terminators v3.1 Cycle Sequencing Kit (Applied Biosystems) and 3500xl Genetic Analyzer (Applied Biosystems). The molecular type of the non-transcribed spacer (NTS) regions of rDNA accumulates high degrees of sequence variations and is available for the detection of these strain variations. In our previous study, the NTS types of the 64 clinical strains used in the present study were classified into 15 molecular types.²⁰

| Primer sequences | Primer names |
|------------------|--------------|
| ITS 5′-AGCCCGGCTTGTGATG-3′ | ITSF |
| ITS 5′-CATTCGCCCTAGGAAGCCG-3′ | ITSR |
| MDR 5′-ATCAAAGGAGCGATGTCAG-3′ | MDRFR |
| MDR 5′-AATAGCAATAAGCCTGTCTTG-3′ | MDRR |

2.3 | Primer design

The primers, ITSF and ITSR (Table 1), were designed based on the nucleotide sequence of the ITS region in rDNA, as previously reported.¹⁹ The primer pair specifically detects Trichophyton species and Microsporum species. TruMDR2, which encodes an ATP-binding cassette (ABC) transporter related to multidrug resistance, was selected as a single-copy control because it was reported to be a single-copy gene in a genome of Trichophyton rubrum²² and was a single copy confirmed by the whole genome sequencing (WGS) of two strains of T. interdigitale (AOKS00000000.1 and AOKY00000000.1, GeneBank®). The primers, MDRF and MDRR (Table 1), were designed based on the published sequence data of TruMDR2 in T. rubrum (AF291822, GenBank®), and WGS data obtained from T. interdigitale (AOKS00000000.1 and AOKY00000000.1, GenBank®).

2.4 | Standard curve of quantitative real-time PCR (qPCR)

Template DNA for the quantitative analysis was prepared from plasmid DNA, constructed using a TOPO® TA Cloning® Kit (Invitrogen). The ITS and MDR region of T. interdigitale was amplified using the primer pairs of ITS and MDR (Table 1), and cloned into the plasmid vector pCR2.1®-TOPO®. The copy number of templates for standard curves was calculated from the size of the cloned plasmid and DNA concentration. Standard curves were generated using 10-fold serial dilutions, yielding samples containing 10² to 10⁷ copies of ITS DNA per reaction. Assays to generate standard curves were performed using the 7900HT Fast Real-Time PCR System (Applied Biosystems) and SYBR® Green PCR Kit (Qiagen) in a total volume of 25 μL containing 5 μL of template DNA, 12.5 μL of SYBR® Green Master Mix and 1 μL of each primer (ITSFR and MDRFR, 12.5 μmol/L). The amplification protocol consisted of 15 minutes of denaturation at 95°C, followed by 40 cycles of denaturation at 95°C for 10 seconds, annealing at 60°C for 30 seconds and extension at 72°C for 10 seconds, with the addition of a dissociation stage for a subsequent melting curve analysis. Amplification efficiency and the correlation coefficient (R²) between the copy number of the template and cycle threshold (Ct) were assessed by linear approximation.

2.5 | DNA extraction and quantification by qPCR

DNA was extracted from all 64 clinical isolates by a mini-prep method¹²,23 with slight modifications. Briefly, a small amount of the
fungal mat was immersed in 200 μL of lysis buffer (200 mmol/L Tris-HCl (pH 7.5), 0.5% (w/v) sodium dodecyl sulphate, 25 mmol/L ethylenediaminetetraacetate and 250 mmol/L NaCl) and ground with a conical grinder. After heating at 100°C for 5 minutes, 100 μL of 3.0 mol/L sodium acetate was added to each homogenate, which were then incubated at 20°C for 20 minutes, followed by centrifugation at 12 000 g for 5 minutes. DNA samples were precipitated from each supernatant with an equal volume of isopropanol. Each precipitate was washed with 70% ethanol, dried and dissolved in 50 μL of distilled water.

Aliquots of 5 μL from DNA were used as the template for qPCR. qPCR was performed under the same conditions as described above.

### 2.6 Calculation of rDNA copy numbers

The rDNA copy numbers of each strain were calculated as the ratio of the template quantity for rDNA to that for TruMDR2. The rDNA copy number was obtained using the following equation: rDNA copy number = (total copies of ITS)/(total copies of TruMDR2).

### 2.7 Homogeneity of rDNA copy numbers

A single-spore culture was performed by the dilution method using five strains of *T. interdigitale* (KMU 6498, 6510, 6524, 6540 and 6547). A small amount of the fungal mat was suspended in physiological saline, and a conidial suspension was obtained by filtration using a cell strainer (Becton Dickinson and Company, Tokyo, Japan). Each suspension was gradually diluted, and an aliquot of each dilution was inoculated onto the Sabouraud dextrose agar plate. More than three colonies of the single-spore culture were selected from each strain, and the rDNA copy number of each colony was assessed by qPCR described above.

### 2.8 Statistical analysis

Student’s t test was used to compare the rDNA copy number of each strain with colony colour and colony morphology. A one-way ANOVA followed by the Tukey-Kramer post hoc analysis was performed to compare rDNA copy numbers and the NTS molecular type in the case of more than three strains of each NTS type.

### 3 RESULTS

#### 3.1 Standard curve of qPCR

A standard curve (ITS primer: $Y = -3.708x + 41.758$, $R^2 = 0.9996$, MDR primer: $Y = -3.489x + 37.544$, $R^2 = 0.9990$) was obtained in a linear range of $10^2$ to $10^7$ copies for the Ct value versus the copy number of cloned ITS and MDR of *T. interdigitale* (Figure 1). As a result of the sequencing of PCR amplicons using ITS and MDR primers, the sizes of amplicons targeting parts of the ITS and TruMDR2 regions were 107 and 138 bp, respectively, in *T. interdigitale*. These sequences completely matched the registered sequences (ITS: FM986778, MDR: AOKS00000000.1 and AOKY00000000.1, GeneBank®).

#### 3.2 Assessment of rDNA copy numbers

The rDNA copy numbers of the 64 *T. interdigitale* isolates were evaluated using TruMDR2 as the reference single-copy gene. The data obtained revealed a range of 24 to 116 copies, with an average and standard deviation (S. D.) of 59 copies ± 16 per genome, and were shown on a histogram (Figure 2). These results demonstrated that rDNA copy numbers were strain-specific and markedly varied for every strain.

![FIGURE 1](image1.png)

Standard curve for cycle threshold (Ct) versus template DNA copies by qPCR. Serial dilutions of plasmid DNA containing the cloned internal transcribed spacer (ITS) region of rDNA (A) and TruMDR2 (MDR) (B) in *Trichophyton interdigitale* were tested by qPCR using sets of ITS and MDR primers. Each point represents the mean of triplicate measurements. The standard deviations of each point were too small to show in the graph.
3.3 Relationships between rDNA copy numbers and strain features

The rDNA copy number, colony colour, colony morphology and NTS type of the 64 clinical isolates are shown in Table 2. Regarding the results of observations of colony features, the colony colour of 58 strains was white, while that of 6 strains was reddish, and the colony morphology of 47 strains was downy to fluffy, while that of 17 strains was powdery. The 64 strains of T. interdigitale were classified into 15 NTS types. The NTS types of C11I, C2II, C4II, C11II, D1II, D1V, D2II, D4II, D12II, D13II, E2II, F2II, K1I, L2II1 and M2II comprised 1, 8, 1, 1, 5, 1, 29, 3, 3, 1, 1, 1 and 1 strains, respectively. The relationships between rDNA and colony colour, colony morphology and NTS type were analysed statistically. The rDNA copy number did not correlate with colony colour, colony morphology or the NTS type (Figure 3A-C).

3.4 Homogeneity of rDNA copy numbers

rDNA copy numbers from different single-spore cultures were calculated as 50 ± 2, 50 ± 2.7, 56 ± 0.6, 60 ± 2.7 and 70 ± 2.5 (mean ± S. D.) in the genomes of KMU 6498, 6510, 6524, 6540 and 6547, respectively (Figure 4). The coefficient of variation (CV, CV = S. D. /mean) of the rDNA copy number in a single strain was calculated to be less than 6%.

4 DISCUSSION

Some rDNA copy number estimation methods were previously developed. These approaches include pulsed-field gel electrophoresis followed by rDNA-specific Southern blotting. rDNA-targeted qPCR or droplet digital PCR, and whole genome sequencing. Recent studies have used qPCR to estimate rDNA copy numbers because qPCR technology offers the fast and reliable quantification of any target sequence in a sample. It also has many advantages over alternative methods, such as low consumable and instrumentation costs, fast assay development times and high sensitivity. In the present study, we developed a measurement method using qPCR that estimates the rDNA copy number of T. interdigitale by designing ITS and MDR primer sequences.

The genomes of most organisms contain multiple copies of rDNA, and the rDNA copy number varies among strains. Previous studies showed that rDNA copy numbers varied between 1 and 15 in Bacteria and Archaea, between 39 and 19,300 in animals, and between 150 and 26 048 in plants. rDNA repeats in the fungal genome were reported to be between 14 and 1442 using 91 species. Investigations on single fungal species revealed that rDNA copy numbers varied among strains. The rDNA copy numbers of L. maculans, S. cerevisiae and A. fumigatus varied between fungal strains. This is a first report of the rDNA copy number in the dermatophytes, focusing on T. interdigitale. The 64 strains showed a range of between 24 and 116 copies in a genome of T. interdigitale. This range of rDNA was within that of other fungal rDNA copy numbers, and rDNA copy number variations were also observed among the strains of T. interdigitale.

As a result of the homogeneity evaluation of rDNA copy numbers using the single-spore culture of T. interdigitale strains, the CV of the rDNA copy number from each strain was less than 6. The standard curve of ITS was created using triplicate measurements at each point. The CV of each point in the standard curve was calculated as between 3 and 7 using the formula of the regression line and Ct value at each point. Thus, CV from the rDNA copy number in a single strain was within those from qPCR measurements. No significant change was detected by this qPCR measurement in the case of short-term cultures, which was consistent with previous findings obtained using A. fumigatus. The rDNA copy number of A. fumigatus remained stable under various environmental conditions, such as morphology, growth temperature, culture age, antifungal exposure and animal infection model organ site (lungs vs kidneys).

No correlations were observed between the rDNA copy number and colony colour, colony morphology or the NTS type in the 64 clinical isolates of T. interdigitale. We previously classified these 64 isolates into 15 NTS types. The NTS regions of rDNA accumulate high degrees of sequence variations, and the detection of these variations is the most frequently used method for the strain typing of dermatophytes. Present study showed rDNA copy numbers varied more than the NTS type. These results suggest the potential of rDNA copy numbers as a sensitive molecular marker for detecting variations among strains of T. interdigitale and may help distinguish between recurrences due to the original strain and a new strain.

The direct KOH examination and fungal culture are gold standards for the diagnosis and evaluations of the outcomes of

(Continues)
The relationship between rDNA copy numbers and characteristics of *Trichophyton interdigitale* strains. Sixty-four strains of *T. interdigitale* were divided by colony colour, colony morphology and the molecular type of the non-transcribed spacer (NTS) region in rDNA. A, Fifty-eight strains showed white colonies, while 6 were reddish. B, Forty-seven strains showed a downy to fluffy morphology and 17 were powdery. C, Sixty-four strains of *T. interdigitale* were classified into 15 NTS molecular types. The NTS types of C1 II, C2 II, C4 II, C11 II, D1 II, D4 II, D12 II, D13 II, E2 II, F2 II, K1 II, L2 II and M2 II comprised 1, 8, 1, 5, 1, 29, 3, 3, 1, 1, 7, 1, 1 and 1 strains, respectively.

The relationship between rDNA and colony colour or colony morphology was analysed using the Student’s t test, and a one-way ANOVA followed by the Tukey-Kramer post hoc analysis was used to examine the NTS type. rDNA copy numbers did not correlate with colony colour, colony morphology or the NTS type.

Tinea pedis.

Tinea unguium.
were quantified using the ITS region of rDNA targeted by qPCR.33 Skin specimens from patients with tinea pedis and tinea unguium developed to overcome this issue using molecular biological techniques. Several approaches have been developed to evaluate the viability of fungi in specimens. Among them, the evaluation method for viability was revealed a correlation between ITS DNA and CFU 48 hours after death. In addition, the amounts of rDNA in toe nail and CFU were correlated with the number of colonies. By combining the investigation of rDNA copy numbers with the rDNA subunit of frequently isolated pathogenic dermatophytes, especially Trichophyton interdigitale and Microsporum canis, several clinical isolates of dermatophytes based on the nucleotide sequence of internal transcribed spacer 1 (ITS 1) in nuclear ribosomal DNA regions. This finding may provide a more detailed understanding of the mechanisms underlying the attenuation and recalcitrance of dermatophytosis caused by T. interdigitale. Therefore, further studies that focus on the rDNA copy numbers of frequently isolated pathogenic dermatophyte species other than T. interdigitale, such as T. rubrum, T. tonsurans, and Microsporum canis, are needed.

In conclusion, we herein developed a method to estimate rDNA copy numbers in the genome of T. interdigitale using qPCR. This is the first study to investigate the copy number of the rDNA subunit in a genome of T. interdigitale. The rDNA copy number of T. interdigitale varied among strains, from 24 to 116 copies per genome, and the rDNA copy number of each strain appeared to be homogeneous.
