Successful DNA replication and packaging of newly synthesized DNA into chromatin are essential to maintain genome integrity. Defects in the DNA template challenge genetic and epigenetic inheritance. Unfortunately, tracking DNA damage responses (DDRs), histone deposition, and chromatin maturation at replication forks is difficult in mammalian cells. Here we describe a technology called iPOND (isolation of proteins on nascent DNA) to analyze proteins at active and damaged replication forks at high resolution. Using this methodology, we define the timing of histone deposition and chromatin maturation. Class 1 histone deacetylases are enriched at replisomes and remove predeposition marks on histone H4. Chromatin maturation continues even when decoupled from replisome movement. Furthermore, fork stalling causes changes in the recruitment and phosphorylation of proteins at the damaged fork. Checkpoint kinases catalyze H2AX phosphorylation, which spreads from the stalled fork to include a large chromatin domain even prior to fork collapse and double-strand break formation. Finally, we demonstrate a switch in the DDR at persistently stalled forks that includes MRE11-dependent RAD51 assembly. These data reveal a dynamic recruitment of proteins and post-translational modifications at damaged forks and surrounding chromatin. Furthermore, our studies establish iPOND as a useful methodology to study DNA replication and chromatin maturation.

permits the isolation and analysis of proteins at active, stalled, and collapsed replication forks. It can also probe the changes that accompany chromatin deposition and maturation following DNA synthesis. We demonstrate the power of iPOND by defining the dynamics of proteins and post-translational modifications in the replisome and on the newly deposited chromatin.

Results

Development of iPOND

Tracking the location of any single replisome in a mammalian cell is not possible, limiting the utility of ChIP-based technologies. To overcome this technical limitation, we used the thymidine analog 5-ethynyl-2'-deoxyuridine (EdU) (Salic and Mitchison 2008), which contains an alkyne functional group. Covalent linkage to a biotin-azide using click chemistry (Moses and Moorhouse 2007) facilitates single-step purification of the EdU-labeled nascent DNA and associated proteins at replication forks (Fig. 1A).

To validate this methodology we first asked whether we could detect replisome proteins. We labeled cells with EdU for 10 min then performed iPOND. We detected proliferating cell nuclear antigen (PCNA), chromatin assembly factor 1 (CAF-1), replication protein A (RPA), and two subunits of polymerase ε (Fig. 1B). These results indicate that iPOND can purify replisome proteins, including those indirectly bound to DNA such as CAF-1 (Shibahara and Stillman 1999). Furthermore, they indicate that iPOND is a highly sensitive methodology. We are able to detect proteins such as POLE2 and POLE3, which are expected to be at a density of only one or two molecules per fork [Fig. 1B]. Thus, unlike immunofluorescence, iPOND does not require high concentrations of proteins within a small nuclear region to track protein localization. Of note, proteins not present at replication forks, such as GAPDH, are not detectable in iPOND captures [data not shown].

In time-course experiments, we detected PCNA and CAF-1 after a 2.5-min pulse of EdU, histones H2B and H3 after 5 min, and the linker histone H1 at 20 min after EdU addition (Fig. 1C). Thus, with short labeling times, we selectively purify proteins at the replication fork, and longer labeling times permit analysis of chromatin assembly. The order of histone deposition supports previous fractionation data indicating that H1 is added 10–20 min after DNA replication to create higher-order chromatin structures [Worcel et al. 1978].

The resolution of this technique depends on the length of the EdU pulse, the rate of DNA synthesis, and the size of the DNA fragments generated after cell lysis. In practice, the first two parameters are the most important, since we consistently obtain DNA fragments of ~150 base pairs (bp) [Supplemental Fig. 1]. In mammalian cells, the rate of DNA synthesis varies between 0.75 and 2.5 kb/min [Herrick and Bensimon 2008]. Thus, a 2.5-min EdU pulse labels ~2–6 kb, although this is likely a significant overestimation, since EdU must enter the cell and be phosphorylated before incorporation into DNA. Thus, iPOND resolution is on the order of a few thousand base pairs.

Importantly, iPOND can be combined with pulse-chase methods to track how proteins assemble and disassemble from a nascent DNA segment with high spatial and temporal resolution. Increasing chase times monitor DNA-associated proteins at greater and greater distances from the moving fork. In these experiments, histone levels remain constant, indicating that the procedure effectively captures a maturing chromatin segment of constant length [Fig. 1D]. However, PCNA and CAF-1 levels purified with the EdU-labeled segment decline with a half-life of considerably <10 min of chase time [Fig. 1D]. These data indicate that iPOND isolates chromatin-associated proteins specifically located at the replication fork, and are consistent with rapid unloading of PCNA and CAF-1 once Okazaki fragment DNA synthesis is complete.
**Analysis of chromatin maturation using iPOND**

Maturation of the new chromatin requires addition and removal of histone post-translational modifications. Newly synthesized histone H4 is acetylated on two lysines (5 and 12), and these evolutionarily conserved marks are removed after deposition (Sobel et al. 1995; Taddei et al. 1999). Our time course experiments indicate that acetylated H4K5 (H4K5ac) is removed rapidly and H4K12ac deacetylation is slightly delayed (Fig. 2A,B). The delay in K12 deacetylation could be due to the activity of chromatin-associated histone acetyltransferases [HATs] that promote the acetylation of this site in some chromatin domains. Indeed, in the presence of the nonselective HAT inhibitor anacardic acid, the rate of H4K12 deacetylation becomes identical to H4K5, with a half-life of <20 min (Fig. 2C,D).

In principle, chromatin maturation—as measured by H4K5,K12 deacetylation—could be coupled to fork progression. To test this possibility, we used high concentrations of hydroxyurea (HU) to stall active replisomes and stop DNA synthesis. HU addition stalls the fork effectively in these cells, since the amount of histone capture does not increase appreciably during the HU treatment (Fig. 2E). Deacetylation of newly deposited H4 proceeds at the same rate regardless of whether DNA synthesis is inhibited. Thus, chromatin maturation can be uncoupled from replisome movement.

The histone deacetylase (HDAC) in human cells that catalyzes the deacetylation of H4K5 and K12 is unknown. HDAC1 and HDAC2 associate with CAF-1 (Ahmad et al. 1999), and HDAC3 is required—perhaps in late S phase or G2—to remove H4K5ac (Bhaskara et al. 2010). Indeed, in pulse-chase experiments, we found an enrichment of HDAC1, HDAC2, and HDAC3 near the fork (Fig. 2A), and the selective class I HDAC inhibitor FK228 (Furumai et al. 2002) prevented deacetylation of H4 (Fig. 2F), suggesting that all three of these HDACs are involved.

**DDR response at stalled replication forks**

HU treatment causes DDR activation to stabilize the stalled fork and induce a cell cycle checkpoint. Previous studies suggest that HU-stalled forks remain stable and competent to resume DNA synthesis for several hours; however, eventually, the stalled fork collapses and DSBs are formed (Petermann et al. 2010). To further examine this process, we monitored recruitment and modification of proteins at stalled forks. The amounts of PCNA and CAF-1 that are captured at the stalled fork decrease initially after adding HU to the medium, and then reach a steady state level of between 20% and 30% of that found at an elongating fork (Fig. 3A). This PCNA pattern is likely due to unloading of PCNA from the completed Okazaki fragments. We detected RPA associated with the fork both before and after HU addition (Fig. 3A). The amount of RPA detected remained constant even though RPA accumulates at stalled forks (Cimprich and Cortez 2008). This discrepancy is explained because RPA binds only to the single-stranded, template strand of DNA, which lacks incorporated EdU. Therefore, iPOND detects only the RPA immediately adjacent to the newly synthesized dsDNA (Supplemental Fig. 2).

In these experiments, we noticed that at 120 and 240 min after addition of HU, the electrophoretic mobility of RPA decreased, consistent with phosphorylation (Fig. 3A). RPA S33 phosphorylation could be detected within 10 min of HU addition, and S4/S8 phosphorylation appeared at 2 h.

**Figure 2.** HDACs are enriched at replication forks and deacetylate newly deposited histone H4 regardless of fork movement. (A–E). Cells were labeled with EdU for 10 min followed, by a chase into thymidine-containing medium for the indicated times prior to performing iPOND. (B) Quantitation of H4 acetylation levels compared with total H4 in the click reaction samples from three independent experiments. Error bars in all figures are standard deviations. (C,D) Anacardic acid (30 μM) was added to the indicated samples. (E) HU (3 mM) was added to the indicated samples. (F) Cells labeled with EdU were chased into 3 mM HU medium with or without 100 nM FK228 prior to performing iPOND.
observed a marker for DSBs (Dickey et al. 2009). However, we noticed that the rapid phosphorylation of H2AX near the fork saturates within 30 min; however, global levels continue to increase (Fig. 3B, cf. the click rxn lanes and the input lanes). Therefore, we hypothesized that the global increase stems from γH2AX spreading from the stalled fork, as is observed near DSBs (Berkovich et al. 2007; Savic et al. 2009). To test this hypothesis, we first labeled cells with EdU, then chased with thymidine for various lengths of time to extend the distance between the EdU-labeled fragment and the fork, and finally added HU to stall the fork. We again observed maximum γH2AX at the fork 30 min after HU addition; however, the chromatin region distant from the fork contained low but detectable levels of γH2AX that increased when examined at 60 min after HU addition (Fig. 4A, cf. lanes 4–6 and 7–9). A more detailed analysis revealed that the density of γH2AX gradually declined as a function of distance from the stalled fork (Fig. 4B,C). Compared with the saturated density at the fork, the γH2AX density decreased approximately twofold for every 15 min of thymidine chase time when cells were treated with HU for 1 h. By 2 h, we observed increased γH2AX density in all chromatin segments analyzed, suggesting that γH2AX spreading contributes significantly to the global change in γH2AX levels.

To examine the chromatin at a single location distant from the fork, we repeated this experiment holding the thymidine chase time constant at 30 min, and treated with HU for varying times. We observed a steady increase in γH2AX at this distance from the fork (Fig. 4D). Importantly, these results indicate considerable spreading of the γH2AX signal even shortly after fork stalling. Assuming a conservative rate of fork elongation of 1 kb/min, these data imply that, within 1 h of fork stalling, γH2AX spreads to include a large domain containing tens of thousands of base pairs of DNA.

To identify the kinases that phosphorylate H2AX adjacent to the stalled fork and that promote spreading, we used small molecule kinase inhibitors. The selective DNA-PK and ATM inhibitors NU7441 (Leahy et al. 2004) and KU55933 (Hickson et al. 2004) had minimal effects on the spreading or total levels of γH2AX induced by a short (30- to 60-min) HU treatment (Fig. 5A; Supplemental Fig. 3A). However, these inhibitors did significantly reduce γH2AX levels at all chromosomal positions relative to the fork in cells treated with HU for 4 h (Fig. 5B,C; Supplemental Fig. 3B). These results indicate that DNA-PK/ATM contributes to maintenance and spreading of γH2AX at persistently stalled forks. In contrast,
treatment with caffeine, which preferentially inhibits ATR [Sarkaria et al. 1999], significantly reduced γH2AX formation and spreading shortly after the fork is stalled (Fig. 5D). These results are consistent with a model in which ATR phosphorylates H2AX at a stalled fork and promotes initial spreading. At later time points, when DSBs likely form at the fork, ATM and DNA-PKcs maintain and further propagate the H2AX phosphorylation (Supplemental Fig. 4).

Discussion

Previous studies of the replisome and DDR responses at stalled forks relied largely on immunofluorescent imaging to track protein localization. While useful, immunofluorescence has the significant disadvantages of low resolution and low sensitivity. For example, proteins that exist at only single-copy levels at replication forks cannot be tracked with immunofluorescent imaging. In contrast, iPOND technology has dramatically improved sensitivity,
allowing us to detect even proteins such as polymerases. Furthermore, combining iPOND with pulse-chase methods provides high spatial and temporal resolution of protein dynamics. Finally, iPOND also facilitates analysis of post-translational modifications, which is often impossible with immunofluorescent imaging due to poor antibody quality or specificity.

Recently, the Helleday group (Petermann and Helleday 2010) isolated CldU-labeled DNA using an antibody to show that Rad51 is bound to recently synthesized DNA. However, they used a 40-min labeling time, so it is unclear whether this method is sufficiently sensitive or specific to produce high spatial and temporal resolution like iPOND. Also, unlike CldU-IP, iPOND does not require ssDNA to permit antibody access to an antibody epitope, and the biotin–streptavidin purification procedure is compatible with highly stringent conditions [1% SDS and 1 M NaCl], thereby improving specificity.

iPOND is an ensemble methodology. Thus, it provides an average picture of events in different cells at stalled forks throughout the genome. iPOND can be combined with cell synchronization to examine replication and chromatin maturation in early and late replicating genomic regions. In principle, iPOND should be applicable to any process involving DNA synthesis, such as analysis of DNA excision repair.

A disadvantage of iPOND over ChIP methods is the lack of a PCR amplification step. Thus, much larger amounts of input material are necessary to achieve sufficient protein for detection. Fortunately, the covalent coupling of EdU and biotin during the click reaction permits a single-step, highly efficient purification in stringent buffer, salt, and detergent conditions. A significant advantage of iPOND compared with ChIP is its compatibility with unbiased screening approaches. We anticipate coupling iPOND to mass spectrometry to identify all proteins at active and damaged replisomes. Furthermore, mass spectrometry analysis of iPOND-captured histones will facilitate studies of chromatin assembly and maturation.

Chromatin assembly is thought to occur by a stepwise deposition of the core histones, followed by linker histones and changes in post-translational modifications (Probst et al. 2009). Our data confirm this assembly process in vivo in cultured mammalian cells. Furthermore, we found that at least some chromatin maturation processes, such as the removal of acetylation on H4K5 and H4K12, proceed even when decoupled from replisome movement. HDAC1, HDAC2, and HDAC3 are enriched on newly synthesized DNA, and an inhibitor that targets all three of these enzymes prevents H4K5ac and H4K12ac deacetylation. Intriguingly, deacetylation of H4K5ac and H4K12ac occurred at the same rate, but acetyltransferases rapidly reacetylated H4K12, suggesting a specific need for this modification in some chromatin domains.

In the yeast Saccharomyces cerevisiae, H3K56 acetylation is also associated with newly deposited histones during DNA replication, and promotes survival in response to replication stress [Masumoto et al. 2005]. We were unable to detect this acetylation mark on newly deposited histones or after HU treatment [data not shown].

This observation is consistent with other human cell studies that found low levels of this post-translational modification in total chromatin that further decreased in response to DNA damage [Tjeertes et al. 2009].

Prominent changes in response to replication stress include protein phosphorylation. Importantly, our data indicate that γH2AX phosphorylation spreads to a large chromatin domain early in the response to fork stalling. This early phosphorylation is catalyzed by ATR and is unlikely to be due to the processing of the fork into a DSB intermediate. Our data are consistent with previous analyses implicating both ATR-dependent [Ward and Chen 2001] and ATR-independent [Brown and Baltimore 2003; Gilad et al. 2010] H2AX phosphorylating activities in response to fork arrest. Most models of ATR function suggest that it is active only when bound to the ssDNA at the stalled fork through an ATRIP–RPA interaction [Cimprich and Cortez 2008], but our data indicate that ATR helps spread the γH2AX signal. One possibility is that the early spreading of γH2AX is due to looping of the newly synthesized chromatin that brings it into proximity of ATR. Alternatively, ATR may have a method of spreading its signal beyond the immediate ssDNA vicinity, similar to the ability of active ATM to spread along the dsDNA away from the DSB end [You et al. 2007]. MDC1 may be involved in such a process [Ichijima et al. 2011; Wang et al. 2011].

Persistent stalling of the fork for longer than 1–2 h causes a switch in the DDR. RPA is hyperphosphorylated on DNA-PK-dependent phosphorylation sites, ATM/DNA-PK catalyzes further γH2AX spreading, and DSB repair proteins like MRE11, KU70/80, and RAD51 accumulate. RAD51 assembly at these persistently stalled forks depends on MRE11 activity, suggesting a requirement for end resection. The end resection may be on the template DNA strand, since we continued to capture EdU-labeled DNA and associated proteins. Resecting the leading strand template would yield a 3’ overhang of newly synthesized DNA, which could be used in recombination-based methods of fork repair and restart [Petermann and Helleday 2010].

Overall, these data provide the first high-resolution, time-dependent analyses of protein dynamics at active, stalled, and collapsed replication forks in mammalian cells. Furthermore, they validate iPOND as a powerful method to study DDRs, chromatin deposition, and chromatin maturation during DNA replication.

Materials and methods

Cell culture

HEK293T cells were cultured in DMEM supplemented with 7.5% FBS. Stable cell lines expressing POLE2-HA and POLE3-HA were generated by retroviral infection and selection in puromycin-containing medium.

Plasmid constructs

POLE2-HA and POLE3-HA retroviral vectors were generated by gateway cloning. pENTR POLE2 and pENTR POLE3 were

Analysis of DNA replication using iPOND
recombined with pLPCX-GW-HA3X (pDC1127) to generate a C-terminal HA-tagged POLE2 and POLE3 retroviral vectors. pDC1127 was created by subcloning a 3XHA epitope into pLPCX between the Not1 and Cla1 restriction sites, then subcloning the gateway cassette containing attR1, ccdB gene, and attR2 as an EcoRV fragment between EcoRI and Not1 sites.

**iPOND**

EdU-labeled sample preparation  HEK 293T cells (~1.5 x 10⁶ cells per sample) were incubated with 10–12 μM EdU [Vanderbilt Synthesis Core]. For pulse-chase experiments with thymidine (Sigma), EdU-labeled cells were washed once with temperature- and pH-equilibrated medium containing 10 μM thymidine to remove the EdU, then chased into 10 μM thymidine. Other chemicals were added to the cell cultures at the following concentrations: HU [3 mM, Sigma], HAT inhibitor anacardic acid [30 μM, Enzo], HDAC inhibitor FK228 [100 nM, kindly provided by Dineo Khabele], Mre11 inhibitor Mirin [100 μM, Sigma], ATM inhibitor [KU55933, 10 μM; AstraZeneca], DNA-PK inhibitor [KU57758, 1 μM, AstraZeneca], and caffeine [10 mM, ICN Biomedicals]. DMSO was used as a vehicle control where appropriate.

After labeling, cells were cross-linked in 1% formaldehyde/ PBS for 20 min at room temperature, quenched using 0.125 M glycine, and washed three times in PBS. Collected cell pellets were frozen at ~80°C, then resuspended in 0.25% Triton-X/PBS to permeabilize. Pellets were washed once with 0.5% BSA/PBS and once with PBS prior to the click reaction.

**Click reaction**  Cells were incubated in click reaction buffer for 1–2 h at a concentration of 2 x 10⁶ cells per milliliter of click reaction buffer. The click reaction buffer contains Invitrogen’s Click-IT cell reaction buffer and cell buffer additive [C10269], 2 mM copper [II] sulfate [CuSO₄], and 1 μM photocleavable biotin-azide [Kim et al. 2009] [kindly provided by Ned Porter]. DMSO was added instead of biotin-azide to the negative control samples (no clk in all figures). Cell pellets were washed once with 0.5% BSA/PBS and once with PBS.

**Cell lysis**  Cells were then resuspended in lysis buffer containing 1% SDS, 50 mM Tris [pH 8.0], 1 μg/mL leupeptin, and 1 μg/mL aprotinin. Samples were sonicated [Micro-tip, Misonix 4000] in a focused sonicator [274:16646–16653].

**Purification**  Streptavidin–agarose beads [Novagen] were washed 1:1 [v/v] twice in lysis buffer and once in PBS. Washed beads were incubated with the samples for 14–20 h at 4°C in the dark. The beads were washed once with lysis buffer, once with 1 M NaCl, and then twice with lysis buffer. Captured proteins were eluted and cross-links were reversed in SDS sample buffer by incubating for 25 min at 95°C. Proteins were resolved on SDS-PAGE and detected by immunoblotting. In most cases, quantitative immunoblotting was performed using the Odyssey infrared imaging system.

**Antibodies**  Antibodies used were as follows: PCNA [Santa Cruz Biotechnology], CAF-1 p60, RPA32, pRPA32 S4/S8, pRPA32 S33, and pSMC1 S966 [Bethyl Laboratories], FK2 [Calbiochem], RAD51, H2B, H2A, H3, H4, H4K5Ac, Ku70, Ku80, HDAC1, HDAC2, and HDAC3 [Abcam], γH2AX, H1 [Millipore], MRE11 [Genetex], H4K12Ac and H4K20me1 [Active Motil], and anti-HA [Covance].

**Determination of DNA fragment size**  To determine DNA fragment size, 5 μL of pre- and post-sonication samples were incubated at 65°C to reverse the DNA–protein cross-links, then incubated with RNaseA and proteinase K. DNA samples were resolved on a 1.5% agarose gel, stained with ethidium bromide, and visualized under UV light. DNA fragment sizes ranged between 100–300 bp. It should be noted that we determined that the CuSO₄ in the click reaction catalyzes cleavage of the phosphodiester bond and assists in generating the small fragment size.
