Abstract: We study the electromagnetic beam reflection from layered structures that include the so-called double-negative materials, also called left-handed metamaterials. We predict that such structures can demonstrate a giant lateral Goos-Hänchen shift of the scattered beam accompanied by splitting of the reflected and transmitted beams due to the resonant excitation of surface waves at the interfaces between the conventional and double-negative materials as well as due to excitation of leaky modes in the layered structures. The beam shift can be either positive or negative, depending on the type of the guided waves excited by the incoming beam. We also perform finite-difference time-domain simulations and confirm the major effects predicted analytically.

1. Introduction

An optical beam totally reflected from an interface between two transparent dielectric media is known to experience a lateral displacement from the point of reflection predicted by geometric optics because each plane wave component of the beam undergoes a different phase change. Such lateral beam shift is usually called the Goos-Hänchen effect \[ \text{1} \]; it occurs at the angles close to the angle of the total internal reflection by the interface, and the beam shift is usually much less than the beam width.

However, much larger beam shifts are known to occur in the layered structures that support surface or guided waves which, when excited, are able to transfer the incoming beam energy along the interface. Such guided waves are not excited in the case of a single interface separating two dielectric media because the phase matching condition between the incident beam and surface waves cannot be fulfilled. However, guided waves can be excited in layered structures when the beam is incident at an angle larger than the angle of the total internal reflection. In this case, the guided waves are also termed leaky waves \[ \text{2} \]. Excitations of leaky waves by scattering of electromagnetic waves are usually realized in two well-known geometries, which are used in the solid-state spectroscopy, also known as the attenuated (or frustrated) total internal reflection experiments. These two excitation geometries are: (i) glass prism-air-dielectric structure, usually called Otto configuration \[ \text{3} \] and (ii) prism-dielectric film-air structure, usually called Kretchmann configuration (see, e.g. Ref. \[ \text{4} \] and references therein).

Recent experimental fabrication \[ \text{5} \] and extensive theoretical studies \[ \text{6} \] of the properties of novel microstructured materials with negative refraction, called double-negative (DNG) materials, as well as left-handed metamaterials, demonstrate that an interface between the conventional and DNG media can support surface waves (or surface polaritons) of both TE and TM polarizations \[ \text{7, 8} \]. Existence of surface waves for all parameters of the interface suggests that they can enhance dramatically the value of the Goos-Hänchen effect for the beam reflection because such surface waves can transfer the energy of the incoming beam along the interface, as was first discussed in Ref. \[ \text{9} \].

The purpose of this paper is twofold. First, we study analytically the manifestation of the giant Goos-Hänchen effect that can be observed in the beam reflection by two types of layered structures that include DNG media. In these geometries, we demonstrate resonant excitation of (i) surface waves at a surface of a DNG medium, and (ii) leaky waves in a structure with a DNG slab. We study the corresponding stationary guided modes in the layered structures, and then demonstrate, by solving the stationary scattering problem, the resonant reflection and transmission due to the excitation of leaky waves in two different geometries. Second, we use the direct numerical finite-difference time-domain (FDTD) simulations \[ \text{10, 11} \] to study the temporal dynamics of the beam scattering and surface wave excitation, and confirm the major predictions of our theory.
2. Lateral beam shift

First, we recall that, in the framework of the scalar theory of the linear wave scattering \[12\], the lateral shift \( \Delta_r \) of the beam reflected by a layered dielectric structure can be defined as follows,

\[
\Delta_r = \frac{d\Phi_r}{dk_x},
\]

(1)

where the index ‘\( r \)’ refers to the beam reflection and \( \Phi_r \) is the phase of the reflection coefficient. The approximation Eq. (1) is obtained with the assumptions that the beam experiences total internal reflection and that the phase of the reflection coefficient \( \Phi_r \) is a linear function of the wave vector component \( k_x \) across the spectral width of the beam.

This lateral beam shift and the Goos-Hänchen effect have been calculated for several cases of beam reflection from layered structures with DNG materials, in particular, for the beam reflection from a single interface \[13\], \[10\] and a periodic structure of alternating right- and left-handed layers \[14\]. Also, the shift of the beam transmitted through a DNG slab has been studied theoretically as well in Ref. \[15\].

However, if the phase \( \Phi_r \) is not a linear function of the wave number \( k_x \) across the spectral width of the beam (e.g., for narrow beams with wide spectrum), the approximate formula (1) for the shift of the beam as whole, strictly speaking, is not valid. In such a case, one can find the structure of both reflected and transmitted beams as follows,

\[
E_{r,t}(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \{R(k_x), T(k_x)\} \tilde{E}_i(k_x) dk_x,
\]

(2)

where \( \tilde{E}_i \) is the Fourier spectrum of the incident beam, and then define the relative shift of the beams, \( \Delta_{r,t} \), by using the normalized first moment of the electric field of the reflected and transmitted beams,

\[
\Delta_{r,t} = \Delta_{r,t}^{(1)},
\]

(3)

where \( a \) is the width of the incident beam.

As a matter of fact, the transverse structure of the reflected and transmitted beams can have a complicated form; and, in general, it can be asymmetric so that the shift defined by Eq. (3) may differ essentially from the value following from Eq. (1).

The case \( \Delta \ll 1 \) corresponds to the beam shift much smaller then the beam width, whereas the case \( \Delta \geq 1 \) is much more interesting, and it corresponds to the so-called giant Goos-Hänchen effect. The second moment of the reflected and transmitted beams, \( \Delta_{r,t}^{(2)} \), defined by Eq. (3), characterizes a relative width of, respectively, the reflected and transmitted beams,

\[
W_{r,t} = \sqrt{\Delta_{r,t}^{(2)}}.
\]

In what follows, we assume, without specific restrictions of generality, that the interface between the first and the second medium is located at \( z = 0 \) and that the incident beam is Gaussian and has the beam width \( a \), i.e., at the interface the electric field of the beam has the form \( E_i(x, z = 0) = \exp(-x^2/4a^2 - ik_{z,0}x) \). The angle of incidence, \( \phi \), of the beam is defined with respect to the normal to the interface so that the wave number component along the interface in the medium from which the beam is incident is \( k_{z,0} = k_1 \sin \phi \) and the corresponding wave number in the medium into which the transmitted beam propagates is \( k_1 = \omega \sqrt{\varepsilon_1 \mu_1}/c \).
3. Excitation of surface waves

We consider a two-dimensional, three-layered structure schematically depicted in Fig. 1(a), where the input beam, is incident from an optically dense medium (the first medium) with \( \varepsilon_1 \mu_1 > \varepsilon_2 \mu_2 \) at an incident angle larger than the angle of total internal reflection. Medium 2 represents a gap layer of width \( d \) that separates Medium 1 and 3. We assume that the third medium consists of a DNG metamaterial which possesses both negative real parts of the dielectric permittivity \( \varepsilon_3 \) and magnetic permeability \( \mu_3 \). The interface between medium one and two generates reflected and transmitted beams. The interface between medium two and three can support surface waves which are excited resonantly when the tangential component of the wave vector of the incident beam coincides with the propagation constant of the corresponding surface polariton. In such a case, the surface wave can transfer the energy along the interface leading to an effective enhancement of the lateral shift of the reflected and transmitted beams.

In the geometry shown in Fig. 1 the reflection coefficient \( R = R(k_x) \) for the TE-polarized monochromatic \( \sim \exp(\imath \omega t) \) plane wave is defined as

\[
R = \frac{(\alpha_1 + 1)(\alpha_2 + 1) - (\alpha_1 - 1)(\alpha_2 - 1)e^{2\imath k_x d}}{(\alpha_1 - 1)(\alpha_2 + 1) - (\alpha_1 + 1)(\alpha_2 - 1)e^{2\imath k_x d}},
\]

where \( \alpha_i = k_{z_i} \mu_i / k_{z_2} \), \( k_{z_i} = (\omega^2 \varepsilon_i \mu_i / c^2 - k_x^2)^{1/2} \), for \( i = 1, 2, 3 \), and \( c \) is the speed of light in vacuum. For definiteness, we consider only the case of TE polarized waves, but our studies indicate that the results are qualitatively similar for the case of TM polarized waves.

Using Eq. 4, we can show that the phase of the reflection coefficient has an abrupt change when \( k_x \) coincides with the wave vector of a surface wave supported by the interface between medium two and three. Thus, larger values of the lateral beam shift are expected at angles of incidence for which the beam spectrum contains the wave vector components having the same \( k_x \) as the propagation constant of the surface waves. As was shown recently, both forward and backward surface polaritons can exist at the DNG interface \( \delta \), depending on the effective parameters \( X = |\varepsilon_3| / \varepsilon_2 \) and \( Y = |\mu_3| / \mu_2 \). Excitation of the forward surface waves results in the energy transfer in the direction of incidence. A negative shift of the reflected beam will be observed for the excitation of the backward surface waves, this case corresponds to the conditions \( XY > 1 \) and \( Y < 1 \).

We chose the following parameters for the media in our three-layered structure: \( \varepsilon_1 = 12.8, \mu_1 = \varepsilon_2 = \mu_2 = 1, \varepsilon_3 = -3, \mu_3 = -0.5 \). The propagation constant of the surface waves, \( h \), is
found from the relation
\[ h^2 = \varepsilon \mu \frac{\omega^2}{c^2} \frac{Y(Y - X)}{(Y^2 - 1)}, \]
and for this case the surface waves at the interface are backward propagating. Figures 2(a,b) show the dependence of the relative beam shift \( \Delta \) and the beam width \( W \) on the angle of incidence when \( a/\lambda_0 = 100/2\pi \) and \( d/\lambda_0 = 3/2\pi \), where \( \lambda_0 \) is the free-space wavelength. A distinctive resonant dependence of the beam shift is observed, and the maximum of this shift corresponds to the point of maximum shift in (a).

In the beam profiles shown in Fig. 2 we observe that the reflected beam has a distinctive double-peak structure. The first peak corresponds to a mirror reflection, while the second peak is shifted relative to the point of incidence. The latter can be explained by the excitation of surface waves. At the resonance, this lateral beam shift becomes larger than the width of the beam itself. The double-peak structure appears only for relatively narrow beams for which the beam spectrum is wider than the spectral width of the surface wave mode, the latter can be found as the width of the resonance shown in Fig. 2(a). The components of the beam spectrum outside this region are reflected in the usual mirror-like fashion. The spectral components of the beam near the resonance transform into an excited surface wave, and they are responsible for the appearance of the second peak in the shifted reflected beam. For wider beams, such that their spectrum completely falls into the spectral region of the surface wave mode, only the shifted peak appears. With an increase of the beam width, though, the relative beam shift decreases due to the fact that the absolute shift of the beam grows slower than the beam width.

Figures 2(c,d) show the relative beam shift and width versus the normalized thickness of the gap medium. The resonances presented in Figs. 2(c,d) can be explained with the help of a simple physics argument. Indeed, when the gap separating medium 1 and 3 is absent (i.e. \( d = 0 \)) or very small, no surface waves are excited; and the beam shift is negligible. Increasing the width of the gap medium, we increase the quality factor of the surface mode, and thus increase the shift of the reflected beam. Similarly, for large values of \( d \) surface waves are not excited, and the shift of the reflected beam becomes small again.

To gain a deeper understanding of the physical mechanism for the large values of the Goos-Hänchen shift in the case when the layered structure includes the DNG medium, we calculate...
the energy flow distribution and compare it with the results for a conventional (or right-handed) medium [16]. From the analysis of the energy flow structure, we conclude that the surface wave excited at the interface has a finite extension and a distinctive vortex-like structure as predicted earlier in Ref. [9] and other studies. This surface wave transfers the energy in the negative direction and, consequently, the energy is reflected from the interface as a shifted beam.

To make our predictions more realistic, we included the effect of losses into our analysis, which are always present in DNG metamaterials. We introduce losses by introducing imaginary parts into the dielectric permittivity $\varepsilon_3$ and magnetic permeability $\mu_3$. In particular, we take $\mathcal{I}m(\mu_3) = -2 \cdot 10^{-5}$ and vary the imaginary part of $\varepsilon_3$. We notice that the losses in the DNG medium primarily affect the surface waves. Therefore, the major effect produced by the losses is observed for the strongly shifted beam component.

When the beam is narrow, i.e. its spectral width is large, only a part of the beam energy is transferred to the surface wave, while the other part is reflected. This case is shown in Figs. 3(a,b). In this case an increase in the loss, i.e. the increase of the absolute value of $\mathcal{I}m(\varepsilon_3)$, results in the suppression of the second peak present in the reflected beam which, as noted above, is due to the surface wave excitation [9].

Finally, we perform direct numerical FDTD simulations to study the temporal dynamics of the surface wave excitation. The FDTD simulator used in these calculations is described in [10, 11]. The DNG medium is modelled with a lossy Drude model for both the permittivity and permeability. The cell size was set at $\lambda_0/100$ to minimize any effects of the numerical dispersion associated with the FDTD method. We launch the beam with a waist $\lambda_0$ at the incident angle $21.17^\circ$ to observe the backward wave excitation, i.e., this incident angle corresponds to the resonant surface wave excitation. The medium parameters are the same as those used in Fig. 2(a,b). The intensity of the electric field at the final step of the numerical simulations is shown in Fig. 4(a). In the top part of this figure we observe the interference of the incident and reflected beams. Though it is not easy to discern the double-peak structure of the reflected beam, one can clearly see the surface wave excited at the boundary between air and DNG media. The
Fig. 4. Distribution of the electric field after the excitation of (a) backward surface wave (665K), and (b) forward surface wave (815K).

Fig. 5. Temporal variation of the amplitudes of the incident (solid) and surface (dashed) waves.

The fact that the maximum of surface wave is shifted in the direction opposite to the direction of the incident wave indicates that the excited surface wave is backward. The temporal variations of the amplitudes of the incident and surface waves are shown in Fig. 5.

In order to observe the process of the excitation of the forward surface wave, we take the medium parameters with a different set of values (see, e.g., Ref. [8]): \( \varepsilon_1 = 12.8, \mu_1 = \varepsilon_2 = \mu_2 = 1, \varepsilon_3 = -0.5, \mu_3 = -2, \) and \( d = \lambda. \) Using the theoretical approach discussed above, we find that for an incident beam having a waist \( \lambda_0, \) the resonant excitation of the forward surface waves should be observed with the incident angle of 16.32°. The distribution of the electric field intensity calculated by the FDTD simulator is shown in Fig. 4(b). Here, we can identify clearly
4. Excitation of slab modes

Now we consider the five-layer structure geometry shown in Fig. 6(a). The first and fifth slabs have the material parameters $\varepsilon_1$ and $\mu_1$. There are two gap slabs with material parameters $\varepsilon_2$ and $\mu_2$. The middle slab has the material parameters $\varepsilon_3$ and $\mu_3$. Without the slabs one and five (i.e. when $d \to \infty$) the structure reduces to an isolated slab. When this slab is a DNG medium, it is known to support guided modes. The presence of the optically dense medium makes these guided slab modes leaky [2], because these waves can now tunnel outside the guided region. The dense media on both sides of the center slab make it possible for such leaky waves to radiate in both directions.

For our studies, we use the same parameters as we did for the three-layered structure discussed in the previous section. The properties of the guided modes supported by a DNG slab have been analyzed earlier in Ref. [17]. Depending on the thickness of the DNG medium, the slab can support either one or several guided modes. Figure 6(b) shows the dependence of the wave number of the TE-polarized modes as a function of the slab thickness.

Reflection and transmission coefficients for the scattering of monochromatic plane waves by a layered structure can be calculated with the help of the transfer-matrix method (see, e.g. Ref. [18]). We take the slab thickness $L = 5\lambda / 2\pi$, so that both symmetric and antisymmetric modes can exist in this layered structure. Additionally, we select angles of incidence so that $k_x$
Fig. 7. Dependence of the relative shifts of (a) reflected and (b) transmitted beams versus the angle of incidence, for $L = 5\lambda_0/2\pi$ and $d = \lambda_0$, and several values of the waist of the incident beam $a$: $a = \lambda_0$ (dotted), $a = 5\lambda_0$ (dashed), and $a = 10\lambda_0$ (solid). The vertical lines indicate the position of the slab eigenmodes. The insert shows an enlargement of the domain marked by a dashed box in the main figure.

will be the same as one of the guided modes, as was discussed above, to achieve large values of the lateral shift of the reflected beam.

Figure 4 shows the shift of the reflected and transmitted beams, calculated with the help of Eq. (3), as a function of the angle of incidence. There is a distinctive resonant behavior for this shift. For a wide beam, the resonance maxima correspond to the phase matching condition $k_{x0} = h$; and, measuring the position of such resonances, we can determine the thickness of the DNG slab with a precision exceeding a wavelength. However, the two-peak structure of the resonances disappears for narrower beams because such beams have a wide angular spectrum and, hence, both modes are excited simultaneously. Moreover, the relative shift of the transmitted beam can be much larger than that of the reflected beam. This happens because the transmitted wave is composed only of a beam emitted by the excited leaky wave whereas the reflected beam consists of two parts: this leaky wave part and the mirror-like beam reflected from the structure. In contrast, the positive resonances in the low wave number gap regions correspond to the resonant reflections from that gap. The resulting fields can also be treated as excitations of leaky waves that are guided by the air gaps.

Figure 8 shows the shift of the reflected and transmitted beams versus the normalized thickness $d$ of the gap slabs. The resonant-like behavior of these dependencies can be explained in the same way as was done for the case of surface waves. If the gap is absent, no leaky waves are excited and, therefore, the shift of the reflected beam is much smaller then the incident beam width. If we increase the width of the gap separating the medium one and three, we increase effectively the quality factor for the excitation of guided modes, thus increasing the propagation distance of such waves and, hence, the lateral shift of the reflected beam. For large widths of the gap, the reflected beam spectrum is much wider than the spectrum of the leaky waves and, as a result, only a small part of the beam energy can be transferred to the guided waves, making the resulting beam shift small.

Figures 8(c,d) show the dependence of the beam shift on the width of the incident beam. A
Fig. 8. Dependence of the relative shift of the (a) reflected and (b) transmitted beams versus the thickness $d$ of the air gaps between the DNG slab and the high-index slabs when $L = 5\lambda_0/2\pi$, $a = \lambda_0$, and $k_{in} = 1.1862\pi/\lambda_0$. Dependence of the relative shift of the (c) reflected and (d) transmitted beams versus the waist $a$ of the incident beam when $L = 5\lambda_0/2\pi$, $d = \lambda_0$, and $k_{in} = 1.1862\pi/\lambda_0$.

Fig. 9. Intensity distribution of the electric field for the excitation of (a) backward guided waves (430K) and (b) forward leaky waves guided by the air gaps (1.5M).
change of the width of the incident beam modifies its spectral extent, thus it changes the ratio of the energy carried by the mirror-like reflected and leaky-wave radiated beams.

We have performed direct numerical FDTD simulations of the temporal dynamics for the excitation of the guided waves in the five-layer structure. Samples of these results are shown in Figs. 9(a,b) where two snapshots in time of the electric field intensity distribution at the end of the simulations are given. In particular, Fig. 9(a) shows the excitation of the backward guided waves. The air gap thickness here was chosen to be $\lambda_0/2$ in order to decrease the quality factor of the guided modes and to obtain a better coupling with the radiative modes. The excited guided wave has a vortex-like structure of the energy flow, as predicted earlier in Ref. [17]. The structure of the $x$-component of the instantaneous Poynting vector is shown as a contour plot in Fig. 10(a). It shows that the energy inside the DNG slab flows in the direction opposite to energy flow in dielectrics. Figure 10(b) presents the cross-section transverse to the interfaces shown in Fig. 10(a) at the middle point of the simulation domain. It shows explicitly the negative energy flow inside the DNG slab waveguide.

Finally, Fig. 9(b) shows the snapshot in time of the distribution of the electric field intensity at the end of the simulation in the case when the excitation of the leaky waves are guided by the air gaps. The results demonstrate that the electric field in this case is mostly concentrated in the air gaps. This explains the positive energy transfer, and the overall positive shift of the reflected and transmitted beams.

5. Conclusions

We have analyzed the scattering of an obliquely incident Gaussian beam by a multi-layered structure that includes a double-negative (DNG or left-handed) medium. We have demonstrated that a rich variety of surface and guided waves supported by these multi-layered structures hav-
ing both double-positive (DPS or right-handed) and DNG media can result in a giant lateral shift of the beam reflected from it. We have emphasized that this effect is due to either the resonant excitation of surface waves (surface polaritons) at the interface between the conventional DPS and the unconventional DNG materials, or due to the resonant excitation of guided and leaky modes in the DNG slabs. For the resonant excitations of guided waves, the reflected beam has a well-defined double-peak structure, where one peak represents the mirror-like reflection, and the second one appears due to a lateral beam shift from the point of the mirror-like reflection, and it is produced by the excited surface waves. The lateral beam shift can be both positive and negative, depending on the type of the surface waves supported by the structure and excited by the incoming beam. Many of those predictions hold in the presence of losses in the DNG material that has been included in our analysis as well. We have also performed a series of direct finite-difference-time-domain numerical simulations to model the temporal dynamics of the beam scattering in both types of the multi-layered structure guided-wave geometries and have confirmed the major effects predicted analytically for the time harmonic, stationary problem.
