TECHNICAL REPORT

Preparation of alumina ceramics from a slurry with cellulose nanofibers

The effect of adding cellulose nanofibers (CNFs), which are among the new materials attracting attention recently, to aqueous alumina (Al₂O₃) slurry was evaluated in order to investigate the possibility of using CNFs as a new forming aid. Al₂O₃ slurries with a small amount of CNFs (>0.1%) showed significant thixotropy. The slurry with 0.1% CNFs was cast in a gypsum mold, and Al₂O₃ green bodies with no cracks could be prepared after demolding and drying in air. Then Al₂O₃ sintered bodies with no cracks could be obtained after heating at 1600°C for 2 h. The densities of the green bodies and sintered bodies prepared from the slurry with CNFs were lower, however, than those prepared from the slurry without CNFs. In addition, the bending strength of sintered bodies prepared from the slurry with CNFs was also lower than that of those prepared from the slurry without CNFs. In order to prepare dense Al₂O₃ sintered bodies, it will be necessary to improve the density of the green bodies prepared from slurry with CNFs added.

1. Introduction

Cellulose nanofibers (CNFs), which are of tree origin, are attracting attention due to their excellent physical properties, such as high specific strength and a low thermal expansion coefficient. In recent years, industrially available CNFs have been developed by physically and chemically fibrillating cellulose, one of the constituents of trees. They are several nanometers in width and several micrometers in length. They can also easily be dispersed in water. Consequently, they have been studied extensively as a new material for uses as thickeners and reinforcing fibers. However, there are few studies on the application of CNFs to ceramics processes. If CNFs have potential as a wet-forming aid for ceramics, they can be expected to be widely used in the wet-forming processes. One of the positive expectations is that the addition of CNFs to slurry might suppress the generation of cracks in samples during drying shrinkage. On the other hand, CNFs might reduce the density of the green bodies. Furthermore, CNFs in green bodies might exert a negative influence on the sintered bodies (for example, generation of cracks) due to thermal decomposition during heating. In order to apply CNFs as an additive for ceramics processing, therefore, especially as a forming aid, it will be necessary to acquire various basic data on the process from raw materials preparation to sintered bodies production.

In this study, CNFs were applied to wet forming of alumina (Al₂O₃) ceramics, which are typical oxide ceramics that are widely used as structural components. First, aqueous Al₂O₃ slurries with CNFs were prepared, and green bodies were then made by slip casting them using gypsum molds. After casting, the green bodies were fired to prepare Al₂O₃ sintered bodies. Finally the characteristics of the slurries, the green bodies and the sintered bodies were evaluated.

2. Experimental procedures

Aqueous Al₂O₃ slurries were prepared by mixing commercially available high-purity Al₂O₃ powder (160SG-4, Al₂O₃ > 99%, 6 m²/g, Showa Denko KK), distilled water, water-soluble acrylic dispersant and CNF aqueous dispersion (REOCRYSTA, water dispersions of 2% CNFs, Dai-ichi Kogyo Seiyaku Co., Ltd.). A planetary centrifugal vacuum mixer without mixing media was used to mix these materials. The composition of the slurries was 100 parts by weight of Al₂O₃ powder, 25 parts by weight of water (containing water of CNF aqueous dispersion), 1 part by weight of water-soluble acrylic dispersant and 0.1 or 0.2 parts by weight of CNFs. By comparison, a slurry without CNFs was also prepared. Al₂O₃ slurries with 0.1 and 0.2 parts by weight of CNFs are referred to as slurry with 0.1% CNFs and with 0.2% CNFs, respectively. Green
bodies were prepared by casting the slurries in gypsum molds, followed by demolding and drying the samples at room temperature in air. With a gypsum mold, it is possible to cast a green body approximately 9 cm in length, 6 cm in width and less than 1 cm in thickness. After drying, the green bodies were heated at 5 °C/min and fired at 1600°C for 2 h in air. The green bodies and sintered bodies prepared from the slurries with/without CNFs are referred to as green bodies and sintered bodies with/without CNFs, respectively.

The thermal decomposition behavior of CNFs was measured using a simultaneous differential scanning calorimetry (DSC)-thermogravimetric analysis (TGA) instrument (SDT Q600, TA Instruments). REOCRISTA, dried in air at 80°C, was provided for the measurements. Measurement was conducted under conditions of a heating rate of 10 °C/min from room temperature to 1000°C in air flow (100 ml/min). The slurry characteristics were evaluated using a spindle type viscometer. The rotating speed of the rotor of the viscometer was varied from 0.3 to 60 rpm, and the (apparent) shear stress with respect to each (apparent) shear rate was measured. The flow curves of the sample slurries were then acquired from the measurements conducted while increasing and decreasing the rotating speed. The density of the green bodies was calculated based on their size and weight. The bulk density of the sintered bodies was measured by the Archimedes method. The relative density of the sintered bodies with respect to the density of Al₂O₃ (3.98 g/cm³) was also calculated. The bending strengths of the sintered bodies produced from the slurries with/without CNFs were measured by a 4-point bending method following JIS-R1601. The number of the respective test pieces was five, respectively. The microstructures of the green bodies and the sintered bodies were observed by scanning electron microscopy (SEM).

3. Results and discussion

Figure 1 shows the thermal analysis results for the CNFs dried at 80°C. From the TG curve, weight loss was observed at from room temperature to about 100°C and from about 220°C to about 300°C. Another weight loss with an exothermic peak was observed at around 600°C. The weight loss to about 100°C was due to volatilization of water attached to CNFs. The weight loss starting from about 220°C corresponds to the dehydration reaction of cellulose. This result is consistent with the CNFs remaining stable up to 200°C. The weight loss and exothermic peaks at around 600°C are due to thermal decomposition of the CNFs.

Figure 2 shows the flow curves of the Al₂O₃ slurries with/without CNFs. In the flow curves of the slurry without CNFs, the shear stress gradually increased with increases in the shear rate, and the curve at the time of acceleration almost agreed with the curve at deceleration. On the other hand, when CNFs were added, a marked increase in shear stress was observed along with a slight increase in shear rate. In addition, the curve during acceleration did not coincide with that during deceleration, and a hysteresis loop was observed. The area drawn by this hysteresis loop increased with increases in the amount of CNFs added. That is, the thixotropy of the Al₂O₃ slurries became increasingly remarkable with increases in the amount of CNFs added.

In this study, green bodies were prepared from slurry with 0.1% CNFs, since slurry with 0.2% CNFs has low fluidity and proved difficult to cast in gypsum molds. No cracks were observed on the surfaces of the obtained green bodies with CNFs shown in Fig. 3(a). No cracks were observed on the surfaces of the green bodies without CNFs, either. Thus, the effect of CNFs as reinforcing fibers was not clarified. In order to further clarify the effect of CNFs as reinforcing fibers, comparison under more severe conditions, such as rapid drying in the oven, a lower Al₂O₃ content in the slurry, etc., needs to be conducted as a future task.

The density of the green bodies with CNFs (2.27 g/cm³) was lower than that of those without CNFs (2.43 g/cm³). Figure 4 show SEM photographs of the fracture surfaces of green bodies with/without CNFs, respectively. Though it was difficult to make a quantitative comparison from the fracture surface observations, the microstructure of the green bodies with CNFs is somewhat looser than that of
those without CNFs, as shown in Fig. 4(b). Observation of CNFs, which were predicted to be dispersed among the Al₂O₃ particles, was attempted, but no fibers that appeared to be CNFs were found, as shown in Fig. 4(b). The CNFs were too small to observe using a conventional SEM. No cracks were observed on the surfaces of the sintered bodies without CNFs or with CNFs, either, as shown in Fig. 3(b). Under the experimental conditions of this study [amount of CNFs added (0.1 part by weight) and heating rate of the samples (5 °C/min)], therefore, it was revealed that there was no cracking due to thermal decomposition of the CNFs.

Table 1. Some properties of Al₂O₃ sintered bodies with/without CNFs

| CNF Content | Density (g/cm³) | (Relative Density) (%) | Flexural Strength (MPa) |
|-------------|----------------|------------------------|------------------------|
| 0.1%        | 3.80           | (95.5)                 | 265.6 ± 15             |
| Free        | 3.92           | (98.5)                 | 403.4 ± 20             |

Table 1 shows the results of the average density and the 4-point bending strength of the sintered bodies. The sintered bodies without CNFs were at almost full density (3.92 g/cm³, relative density 98.5%), but those with 0.1% CNFs showed a slightly lower density (3.80 g/cm³, relative density 95.5%). The average bending strength of the sintered bodies without CNFs was 403.4 MPa, but that of the sintered bodies with 0.1% CNFs was 265.6 MPa. Figure 5 shows SEM photographs of the fracture surfaces of sintered bodies with/without CNFs. As shown in Fig. 5(a), sintered bodies without CNFs have a microstructure containing some voids with diameters of about 1 micron. These voids reduced both the density of the sintered bodies and their bending strength. This Al₂O₃ sintered body with CNFs was fired further at 1600°C for 2 h, but the density of the re-sintered body was 3.80 g/cm³, showing no improvement. This result indicates that the low density of the sintered bodies with CNFs was not due to insufficient firing but to the addition of CNFs.

Improvement of the density of green bodies with CNFs will be necessary to obtain dense Al₂O₃ ceramics. Since slurry with CNFs had higher viscosity and thixotropy, as shown in Fig. 2, movement and packing of Al₂O₃ particles under conditions of CNF dispersion was limited during slip casting in gypsum molds, and the density of the green bodies was reduced as a result. Some techniques are therefore required to enhance the movement and packing of
Al₂O₃ particles. One possible technique is the addition of vibration of the gypsum mold, which is often used in product manufacturing processes. The advisability of using this technique is now under examination.

4. Conclusions
The effect of adding CNFs to aqueous Al₂O₃ slurry was evaluated in order to investigate the possibility of using CNFs as a new forming aid. The slurries with a small amount of CNFs added showed significant thixotropic properties. Both green bodies with no cracks and sintered bodies with no cracks could be prepared, moreover, from slurry with CNFs added. The density of green bodies with CNFs and sintered bodies with CNFs was slightly lower than those without CNFs, however, and sintered bodies with CNFs had lower bending strength. With improvement of the properties of green bodies and sintered bodies containing CNFs and confirming their effectiveness as reinforcing fibers for green bodies, CNFs are expected to become a useful wet-forming aid.
