TATE COHOMOLOGY OF CIRCLE ACTIONS AS A
HEISENBERG GROUP

JACK MORAVA

Abstract. We study the Madsen-Tillmann spectrum $C\mathbb{P}^\infty_{-1}$ as a quotient of
the Mahowald pro-object $C\mathbb{P}^\infty_{-\infty}$, which is closely related to the Tate coho-
mology of circle actions. That theory has an associated symplectic structure,
whose symmetries define the Virasoro operations on the cohomology of moduli
space constructed by Kontsevich and Witten.

1. Tate cohomology of circle actions

1.1 If $E$ is a geometric bordism theory (such as integral homology), its Tate co-
homology $t_\mathbb{T}^*E$ can be constructed by tom Dieck stabilization from the geometric
theory of $E$-manifolds with $\mathbb{T}$-action, the action required to be free on the boundary
[8]. If $E$ is multiplicative, so is $t_\mathbb{T}^*E$; there is a cofibration sequence

$$\cdots \to E^*BT_+ \to t_\mathbb{T}^*E \to E_{-2}BT_+ \to \cdots$$

in which the boundary map sends a $\mathbb{T}$-manifold with boundary to the quotient of its
boundary by the (free) $\mathbb{T}$-action. When $E$ is complex-oriented [eg $MU$ or $HZ$] this
sequence reduces to a short exact sequence which identifies $t_\mathbb{T}^*E$ with the Laurent
series ring $E^*((e))$ obtained by inverting the Euler class in $E^*(BT) = E^*[[e]]$, and
the boundary map can be calculated as a formal residue; more precisely, the
formal Laurent series $f$ maps to the residue of $f d\log E$ at $e = 0$, where $d\log E$
is the invariant differential of the formal group law of $E$. When $E$ is not complex-
orientable, $t_\mathbb{T}^*E$ can behave very differently [4], as the Segal conjecture shows: up
to a profinite completion,

$$t_\mathbb{T}S^0 \sim S^0 \vee S^1 \prod BT/C$$

where $C$ runs through proper subgroups of $\mathbb{T}$.

There is a related but simpler theory $\tau_\mathbb{T}^*E$ defined by manifolds with free $\mathbb{T}$-action
on the boundary alone, which fits in an exact sequence

$$\cdots \to E^* \to \tau_\mathbb{T}^*E \to E_{-2}BT_+ \to \cdots ;$$

ignoring the interior $\mathbb{T}$-action defines a truncation

$$t_\mathbb{T}^*E \to \tau_\mathbb{T}^*E.$$

1.2 It is natural to think of $t_T^* E$ as the $E$-homology of a version [1] of Mahowald’s pro-spectrum $CP^\infty_\infty$, constructed from the inverse system

$$\{CP^\infty_{-k} = Th(-k\eta)\}$$

of Thom spectra defined by the filtered vector bundle

$$\cdots \subset k\eta \subset (k+1)\eta \subset \cdots$$

over $CP^\infty$. To be more precise,

$$t_T E \sim E \wedge S^2 CP^\infty_\infty$$

as spectra, and there is a similar equivalence

$$\tau_T E \sim E \wedge S^2 CP^\infty_{-1}.$$ 

From this point of view, the morphism from $t_T^* E$ to $\tau_T^* E$ is the $E$-homology of the collapse map

$$CP^\infty_\infty \to CP^\infty_{-1}.$$ 

The cobordism class defined by a family of complex-oriented surfaces with a free circle action on its boundary, parametrized by $X$, defines an element of

$$\tau_T^{-2} MU(X_+) = [X_+, CP^\infty_{-1} \wedge MU];$$

the image of this class under the Thom homomorphism from $MU$ to $HZ$ is the homomorphism

$$H^*(CP^\infty_{-1}, Z) \to H^*(X_+, Z)$$

defined by the classifying map of Madsen and Tillmann, sketched below.

1.3 When $E = HZ$, the symmetric bilinear form

$$f, g \mapsto (f, g) = \text{res}_{e=0}(fg \, de)$$

on the Laurent series ring $t_T HZ$ is nondegenerate, and the involution $I(z) = z^{-1}$ on $\mathbb{T}$ defines a symplectic form

$$\{f, g\} = (I(f), g)$$

which restricts to zero on the subspaces of elements of degree $\geq 0$ and $< 0$. The Tate cohomology thus has an intrinsic inner product, with canonical polarization and involution.

The functor $\mathcal{G}$ which sends the commutative ring $A$ to the set of formal Laurent series

$$\mathcal{G}(A) = \{g = \sum_{k \geq 0} g_k x^{k+1} \in A((x)) \mid g_0 \in A^\times, g_k \in \sqrt{A} \text{ if } 0 > k\}$$

(i.e. with $g_0$ a unit and $g_k$ nilpotent when $k$ is negative) in fact takes values in the category of groups, with formal composition of series as the operation. This group of invertible ‘nil-Laurent’ series has a linear representation on the abelian group valued functor $A \mapsto A((x))$, but it is a little too large to be conveniently representable: in a certain sense it is an ind-pro-algebraic analog of the group of diffeomorphisms of the circle.
1.4 It is tempting to interpret $\hat{G}$ as a group of automorphisms of the Tate cohomology, but the most obvious action does not preserve the symplectic structure. Kontsevich-Witten theory suggests a better alternative: there is an embedding

$$e^k \mapsto \gamma_{-k-\frac{1}{2}}(x) : t\tau^*HZ \to \mathbb{R}(\sqrt{x})$$

of symplectic modules, defined using the fractional divided power

$$\gamma_s(x) = \frac{x^s}{\Gamma(1+s)},$$

in which the symplectic structure on the target is defined by

$$u,v \mapsto \{u,v\} = \text{res}_{x=0} u dv.$$

[The reals are a notational convenience: some powers of $\pi$ have been ignored.] Over any field of characteristic zero, the square root of an invertible nil-Laurent series in $x$ is an invertible odd nil-Laurent series in $\sqrt{x}$, and it makes better sense to think of the group $\hat{G}^{-1/2}$ of such series [10 §1.3] as symplectic automorphisms of $t\tau^*HQ \subset \mathbb{R}(\sqrt{x})$. The half-integral shift comes ultimately from the fact that $t\tau^*HZ$ is not Spanier-Whitehead self-dual; rather, its dual is most naturally interpreted as its own double suspension.

2. MADSSEN-TILLMANN AND KONTSEVICH-WITTEN

Madsen and Tillmann construct a map

$$\prod_{g \geq 0} B\text{Diff}(F_g) \to \Omega^\infty \mathbb{C}P_{-1}^\infty$$

which is compatible with gluing of surfaces; in particular, it defines a lax functor from the two-dimensional topological gravity category [11] to a topological category with one object and an $H$-space of morphisms. [Reversing the orientation of a surface corresponds to the involution $I$.] The point of this note is to identify a suitable subgroup of $\hat{G}^{-1/2}$ as the motivic automorphisms of this functor.

2.1 Here is a quick account of one component of [7]: if $F \subset \mathbb{R}^n$ is a closed two-manifold embedded smoothly in a high-dimensional Euclidean space, its Pontrjagin-Thom construction $\mathbb{R}^n_+ \to F$ maps compactified Euclidean space to the Thom space of the normal bundle of the embedding. The tangent plane to $F$ is classified by a map $\tau : F \to \text{Grass}_{2,n}$ to the Grassmannian of oriented two-planes in $\mathbb{R}^n$, and the canonical two-plane bundle $\eta$ over this space has a complementary $(n-2)$-plane bundle, which I will call $(n-\eta)$. The normal bundle $\nu$ is the pullback along $\tau$ of $(n-\eta)$; composing the map induced on Thom spaces with the collapse defines

$$\mathbb{R}^n_+ \to F \to \text{Grass}_{2,n}^{(n-\eta)}.$$

The space $\text{Emb}(F)$ of embeddings of $F$ in $\mathbb{R}^n$ becomes highly connected as $n$ increases, and the group $\text{Diff}(F)$ of orientation-preserving diffeomorphisms of $F$ acts freely on it, defining a compatible family

$$\mathbb{R}^n_+ \wedge_{\text{Diff}} \text{Emb}(F) \to \text{Grass}_{2,n}^{(n-\eta)}$$

which can be interpreted as a morphism

$$B\text{Diff}(F) \to \lim \Omega^n \text{Grass}_{2,n}^{(n-\eta)} := \Omega^\infty \mathbb{C}P_{-1}^\infty.$$
2.2 Madsen and Tillmann show their construction factors through an infinite loop space

\[ Z \times B\Gamma^\infty_\infty \to \Omega^\infty \mathbb{C}P^\infty_{-1} \to Q(\mathbb{C}P^\infty_+) \]

in which the last arrow is defined by collapsing the bottom two-cell in a cofibration

\[ S^{-2} \to \mathbb{C}P^\infty_{-1} \to \mathbb{C}P^\infty_+ . \]

The fiber \( \Omega^2 QS^0 \) of the induced map of loop spaces is torsion, so the rational cohomology of \( \Omega^\infty \mathbb{C}P^\infty_{-1} \) is isomorphic to the algebra of symmetric functions on the subspace of non-negative powers in \( t^\mathbb{Z}_G \). This algebra is thus canonically isomorphic to the Fock representation \([10 \text{§}2.2]\) of the Heisenberg algebra of that symplectic module; but this representation possesses a canonical Virasoro action, defining a homomorphism

\[ H_*(Z \times B\Gamma^\infty_\infty, \mathbb{Q}) \to \text{Symm}(H^*(\mathbb{C}P^\infty_+)) . \]

In Kontsevich-Witten theory the usual generators \( b_k \in H_*(\mathbb{C}P^\infty_+), k \geq 0, \) map to symmetric functions

\[ \text{Trace} \gamma_{-k-\frac{1}{2}}(\Lambda^2) \sim -(2k-1)!! \text{Trace} \Lambda^{-2k-1} = t_k(\Lambda) \]

of a positive-definite Hermitian matrix \( \Lambda \); this leads to a construction of the appropriate twisted Virasoro representation in terms of Schur \( \mathbb{Q} \)-functions \([2,6]\).

2.3 The homomorphism

\[ \lim MU^{*+n-2}(Th(n-\eta)) \to MU^{*-2}(BDiff(F)) \]

defined on cobordism by the Madsen-Tillmann construction sends the Thom class to a kind of Euler class; according to Quillen’s conventions, the Thom class is the zero-section of \( (n-\eta) \), regarded as a cobordism class of maps between manifolds. Its image is the class defined by the fiber product

\[ Z_n \xrightarrow{\text{Grass}_{2,n}} \mathbb{R}^n_+ \wedge \text{Diff Emb}(F) \xrightarrow{\text{Grass}_{2,n}^{(n-\eta)}} ; \]

it is the space of equivalence classes, under the action of \( \text{Diff}(F) \), of pairs \((x, \phi)\), with \( x \in \phi(F) \subset \mathbb{R}^n \) a point of the surface (ie, in the zero-section of \( \nu \)), and \( \phi \) an embedding. The image is thus the element

\[ [Z_n \to \mathbb{R}^n_+ \wedge \text{Diff Emb}] \to MU^{n-2}(S^n BDiff(F)) \]

defined by the tautological family \( F \times \text{Diff Emb}(F) \) of surfaces over the classifying space of the diffeomorphism group. This class is primitive in the Hopf-like structure defined by gluing \([9 \text{§}2.2]\), so the class

\[ \Phi = \exp(th(-\eta)\nu) \in MU^0_0(\Omega^\infty \mathbb{C}P^\infty_+)[[\nu]] \]

doing finite unordered configurations of points on the universal surface (with \( \nu \) a bookkeeping indeterminate) defines a multiplicative transformation

\[ \Phi_* : H_*(Q(\mathbb{C}P^\infty_+), \mathbb{Q}) \to H_*(MU, \mathbb{Q}[[\nu]]) \]
TATE COHOMOLOGY OF CIRCLE ACTIONS AS A HEISENBERG GROUP

2.4 Kontsevich-Witten theory uses a more sophisticated configuration space, which maps the rational homology of $Q(\coprod g \geq 0 \overline{M}_g)$ (suitably interpreted, for small $g$) to a similar ring of characteristic numbers; this homology contains a fundamental class

$$[Q(\coprod \overline{M}_g)] = \exp\left(\sum_{g \geq 0} (g-1) \chi(g)\right)$$

for the moduli space of not necessarily connected curves. Witten’s tau-function is the image of this ‘highest-weight’ vector under the analog of $\tilde{\Phi}^\ast$; it is invariant under the subalgebra of Virasoro generated by operators $L_k$ (of cohomological degree $k$) with $k \geq -1$.

3. AFTERTHOUGHTS, AND POSSIBLE GENERALIZATIONS

3.1 Witten has proposed a generalization of 2D topological gravity which encompasses surfaces with higher spin structures: for a closed smooth surface $F$ an $r$-spin structure is roughly a complex line bundle $L$ together with a fixed isomorphism $L^\otimes r \cong T_F$ of two-plane bundles, but for surfaces with nodes or marked points the necessary technicalities are formidable [5]. The group of automorphisms of such a structure is an extension of its group of diffeomorphisms by the group of $r$th roots of unity, and there is a natural analog of the group completion of the category defined by such surfaces. The generalized Madsen-Tillmann construction maps this loopspace to the Thom spectrum $Th(-\eta^r)$, and it is reasonable to expect that this map is equivariant with respect to automorphisms of the group of roots of unity. This fits with some classical homotopy theory: if (for simplicity) $r = p$ is prime, multiplication by an integer $u$ relatively prime to $p$ in the $H$-space structure of $\mathbb{C}P^\infty$ defines a morphism

$$Th(-\eta^p) \to Th(-\eta^{up})$$

of spectra, and the classification of fiber-homotopy equivalences of vector bundles yields an equivalence of $Th(-\eta^{up})$ with $Th(-\eta^p)$ after $p$-completion. There is an analogous decomposition of $t_T H\mathbb{Z}_p$ and a corresponding decomposition of the associated Fock representations [10 §2.4].

3.2 In an extension of her work Tillmann also considers categories of surfaces mapped to some parameter space $X$, which has interesting connections with both Tate and quantum cohomology. When $X$ is a smooth compact almost-complex manifold, its Hodge-deRham cohomology admits a natural action of the Lie algebra $\mathfrak{sl}_2(\mathbb{R})$, generated [12 IV §4] by the Hodge dimension operator $H$, multiplication by the first Chern class $c_1(X) = E$, and its adjoint $F = *E*$. Recently Givental [3 §8.1] has shown that earlier work of (the schools of) Eguchi, Dubrovin, and others on the Virasoro structure of quantum cohomology can be formulated in terms of (what I like to think of as) $t_T^\ast H(X, \mathbb{R})$, polarized by the twisted involution

$$I_{Giv} = e^{\frac{1}{2}H} e^{-E} I e^{E} e^{-\frac{1}{2}H}.$$

It would be very interesting if this polarization could be understood in terms of the equivariant geometry of the free loopspace of $X$. 
3.3 I owe thanks to R. Cohen, E. Getzler, A. Givental, J. Greenlees, I. Madsen, N. Strickland, and U. Tillmann (at least), for their forebearance in the face of my continued misunderstanding of things they have tried patiently to tell me. I hope I’m finally starting to get it right.
