Implementation of an Automatic Sign Language Lexical Annotation
Framework based on Propositional Dynamic Logic

Abstract

In this paper, we present the implementation of an automatic sign language (SL) sign annotation framework based on a formal logic, the Propositional Dynamic Logic (PDL). Our system relies heavily on the use of a specific variant of PDL, the Propositional Dynamic Logic for Sign Language (PDLSL), which lets us describe SL signs as formulae and corpora videos as labeled transition systems (LTSs). Here, we intend to show how a generic annotation system can be constructed upon these underlying theoretical principles, regardless of the tracking technologies available or the input format of corpora. With this in mind, we generated a development framework that adapts the system to specific use cases. Furthermore, we present some results obtained by our application when adapted to one distinct case, 2D corpora analysis with pre-processed tracking information. We also present some insights on how such a technology can be used to analyze 3D real-time data, captured with a depth device.

Keywords: sign language framework, automatic annotation, propositional dynamic logic

1. Introduction

Research in sign language (SL), both from the point of view of linguistics and computer science, relies heavily on video-corpora analysis (Dreuw et al., 2008). As such, several methods have been developed over time for the automatic processing of both video or other sensor-based corpora (Ong and Ranganath, 2005). Even though these kind of research efforts are usually geared toward recognition, few work has been done in relation to the unification of raw tracked data with high level descriptions (Cooper et al., 2011; Bossard et al., 2004). This calls to a reflection on how we represent SL computationally, from the most basic level.

SL lexical representation research is focused on sign synthesis before than recognition. Works like (Filhol, 2009; Losson and Vannobel, 1998) present the use of geometric lexical descriptions to achieve animation of signing 3D avatars. While their approach is well suited for synthesis, it is not completely adapted for sign identification. Recognition tasks in both natural language processing and computer vision are well known to be error-prone. Also, they are highly susceptible of bumping into incomplete information scenarios which may require some kind of inference, in order to effectively resolve ambiguities. In addition, SL linguistic research has consistently shown the existence of common patterns across different SLs (Aronoff et al., 2005; Meir et al., 2006; Wittmann, 1991) that may be lost with the use of purely geometrical characterizations, as the ones needed in synthesis. This limits the application of these kind of sign representations for automatic recognition, especially since we would want to exploit known linguistic patterns by adding them as properties of our descriptions.

Works like (Kervajan et al., 2006; Dalle, 2006) have acknowledged the necessity of introducing linguistic information to enrich interaction, in an effort to help automatic systems bear with ambiguity. Moreover, the use of additional linguistic data could simplify connections between lexical information and higher syntactic-semantic levels, hence pushing us closer to automatic discourse analysis. However, this has long been out of the scope of synthesis-oriented description languages.

On the side, research in SL recognition has to deal with other important drawbacks not present in synthesis, namely the use of very specialized tools or very specific corpora. This alone can severely impact the portability of a formal, computer-ready, representation out of the original research context, as it complicates the use of the same techniques across different information sources and toughens integration with new tools.

The framework described here is based on previous work presented by (Curiel and Collet, 2013) on the Propositional Dynamic Logic for Sign Language (PDLSL). PDLSL is a formal logic created with the main purpose of representing SL signs in a computer-friendly way, regardless of the specific tools or corpora used in research. Such a representation can potentially reduce the overhead of manually describing SL signs to a computer, by establishing well-known sets of rules that can be interpreted by both humans and automatic systems. This could, incidentally, reduce dependency on thoroughly geometrical descriptions. Moreover, the flexibility of PDLSL lets us combine any kind of information in our descriptions; for example, we can integrate non-manual markers if we have sight and eyebrow tracking, or we can add 3D movements if we are using a depth camera.

In general, we propose an automatic SL lexical annotation framework based in PDLSL descriptions. Ideally, the system will:

- simplify the application of logical inference to recognize PDLSL-described signs;
• characterize and analyze corpora in terms of PDL_{SL} models;

• represent SL with different degrees of granularity, so as to adapt the formulae to the specific technical capabilities available in each use case.

Our framework aims to ease the integration of PDL_{SL} with various corpora and tracking technologies, so as to improve communication between different SL research teams. We expect that this will, in turn, enable the construction of both research and user-level applications in later stages.

The rest of the paper is divided as follows. In section 2., we introduce the basic notions of our formal language, applied to 2D SL video-corpora analysis. Section 3. shows how we can describe SL lexical structures as verifiable PDL_{SL} formulae. Section 4. gives a detailed description of the system’s architecture. Finally, sections 5. and 6. present some preliminary results and conclusions, respectively.

2. Sign Language Formalization with Logic

The Propositional Dynamic Logic (PDL) is a multi-modal logic first defined by (Fischer and Ladner, 1979) to characterize computer languages. Originally, it provided a formal framework for program descriptions, allowing them to be interpreted as modal operators. PDL_{SL} is an specific instance of PDL, based on the ideas of sign decomposition by (Liddell and Johnson, 1989) and (Filhol, 2008). In general, PDL_{SL}’s modal operators are movements executed by articulators, while static postures are interpreted as propositional states reachable by chains of movements.

A propositional state will be none other than a set of distinct atomic propositions. These can be used to represent articulators’ positions with respect to one another; specific configurations; or even their spatial placement within a set of places of articulation. Table 1 shows a brief summary of the atomic propositions defined to analyze 2D corpus data.

| Symbol | Meaning |
|--------|---------|
| $\delta_{\beta_1}$ | articulator $\beta_1$ moves in relative direction $\delta$. |
| $\equiv_{\beta_1}$ | articulator $\beta_1$ trills, moves rapidly without direction. |
| skip | denotes the execution of any action |

Table 2: Atomic actions for PDL_{SL}

Atoms form the core of the PDL_{SL} language, which is presented below in Backus–Naur Form (BNF) by way of definitions 1 and 2.

Definition 1 (Action Language for SL Body Articulators $A_{SL}$).

$$\alpha ::= \pi \mid \alpha \cap \alpha \mid \alpha \cup \alpha \mid \alpha \cdot \alpha \mid \alpha^*$$

where $\pi$ is an atomic action.

Definition 2 (Language PDL_{SL}).

$$\varphi ::= T \mid p \mid \neg \varphi \mid \varphi \land \varphi \mid [\alpha] \varphi$$

where $p$ denotes an atomic proposition and $\alpha \in A_{SL}$.

A more formal presentation of the model basis can be found in (Curiel and Collet, 2013).

3. Extending PDL_{SL} Formulae to Describe Sign Language Lexical Properties

The presented PDL_{SL} language lets us easily codify individual signs by way of our logic formulae. However, during implementation, we noticed the need to extend the original formalism in order to develop a better suited characterization of more general properties. We wanted to represent lexical structures common across multiple signs. With this in mind, we extended PDL_{SL} to include lambda expressions, explained in (Barendsen, 1994), for variable binding. The introduced syntax is presented in definition 3.

Definition 3 (Extended PDL_{SL}).

$$\text{var} ::= \langle \text{uniqueID} \rangle \mid \text{var}, \text{var}$$

$$\varphi_f ::= \varphi \mid \text{var} \mid \neg \varphi_f \mid \varphi_f \land \varphi_f \mid \lambda \text{var}.(\varphi_f) \mid \text{var} = \varphi_f$$

where $\varphi \in$ PDL_{SL}.

The rules of quantification and substitution remain the same as in classic lambda calculus.

Lambdas let us describe properties over sets of PDL_{SL} atoms instead of one. For example, Figure 1 shows two french sign language (FSL) signs, SCREEN_{FSL} and DRIVE_{FSL}. Both can be described as instances of the same underlying common structure, characterized by both hands holding the same morphological configuration while being positioned opposite from one another.

Their common base can be described by way of a lambda expression as shown in example 1.

Example 1 (opposition lambda expression),

$$\text{hands}_\text{config} = \lambda c.(\text{SCREEN} \cap \text{DRIVE})$$

$$\text{opposition} = \lambda c.(\text{SCREEN} \cap \text{hands}_\text{config}(c))$$
In example 1, $F^\text{right}_c$ means that right holds configuration $c$. Atom $F^\text{left}_c$ has the same meaning, but for the left hand. Atom $\text{right}_{\text{fist}}$ means that right hand lies in direction $\leftarrow$ with respect to left, from the annotator’s point of view. In this case we called our expression opposition, because both hands are in opposite horizontal positions from one another.

Once we’ve defined the base structure, the SCREEN$_{FSL}$ and DRIVE$_{FSL}$ signs can be easily described in the database by passing the missing arguments to our lambda expression (as shown by example 2).

**Example 2 (opposition-derived signs).**

SCREEN$_{FSL}$ = opposition(L_FORM)

DRIVE$_{FSL}$ = opposition(FIST_FORM)

In example 2, L_FORM is a morphological configuration of the hand where the thumb and the index fingers are held orthogonally. Similarly, FIST FORM is a configuration where hand is held as a closed fist. Here we just expressed that opposition will substitute each apparition of its first argument with either form, so as to define two distinct signs.

We could also have described both signs as standalone, independent formulæ. However, by describing the common structures across different signs, we are able to cope better with incomplete information in recognition. For example, a generic opposition structure with free variables will correctly hit in states where we can recognize hand positions but no hand configurations (as it’s often the case). This immediately derives into a list of possible signs that could be later reduced with either further processing or with user interaction. In this scenario, standalone formulæ for SCREEN$_{FSL}$ and DRIVE$_{FSL}$ wouldn’t be found, since only using position information isn’t enough to tell them apart.

### 4. Detailed Framework Architecture

The objective of the system is to take an untreated SL video input, either in real time or not, and return a set of satisfied PDL$_{SL}$ formulæ. Moreover, the system has to return a PDL$_{SL}$ model representing any relevant information contained in the video as a labeled transition system (LTS). This can only be fulfilled by adapting the modeling process on-the-fly to the specific characteristics of our data. To achieve this end, our framework generalizes the original architecture proposed by (Curiel and Collet, 2013), shown in Figure 2, so as to enable module swapping depending on the technical needs presented by the inputs.

In the original version, a Tracking and Segmentation module uses the raw data of an automatic hand-tracker on 2D corpora, like the ones presented by (Gonzalez and Collet, 2011), and returns a list of time-intervals classified either as holds or movements. The aforementioned interval list is passed to the Model Extraction Module, which translates each hold and movement into a time-ordered LTS. In the LTS, holds correspond to unique propositional states and movements map to transitions between states. An example of the resulting LTS is shown in Figure 3.

Finally, the Verification Module takes both the generated LTS and a database of PDL$_{SL}$ formulæ to determine which of them are satisfied in the model. As each formula corresponds to a formal description of a sign or property, the module can use logical satisfaction to verify if the property is present or not in the video. The complete process is shown in Figure 4. Finally, the system maps each state
where a formula is satisfied to its corresponding frame interval, so as to generate an annotation proposition.

Figure 4: Example of the different layers processed by an automatic annotation system

4.1 Observer Architecture Design
In order to be able to adapt dynamically to the particular needs of the input data, we devised the observer architecture shown in Figure 5.

The main idea behind this design rests upon two axes:

- the possibility of using several tracking tools, adapted to different kinds of corpora;
- the generation of PDL$$_{SL}$$ models consistent with the information generated by the different trackers.

Moreover, not only do models have to be consistent with every tracker but, as previously stated, not all trackers will give the same information nor track the same features. As such, the framework has to coordinate the loading of the proper modules depending on the corpus and the trackers. This process is entirely done by way of event triggering. The same mechanism enables communication between modules by implementing multiple-reader/single-writer (MRSW) buffers, which allow every module to read their information but let only one of them write modifications. Each time a new modification is written in a MRSW register, an event is issued system-wide to notify of the existence of new information. This event is then available to every module listening to that register’s notifications. For the sake of compatibility, modules are obliged to implement an internal listening thread which can be subscribed to the communication channels of any other module.

In general, the framework establishes development guidelines for the modules of the basic architecture, the one shown on Figure 2, so we can adapt them to specific cases without breaking compatibility. This is achieved by way of generic templates that implement the most basic functionalities of every module. These templates can later be extended to cover the specific cases arising in research; a developer can simply override the critical functionality in each template with their own code. Additionally, modules can register new events within the framework, so as to convey further information (if needed) for particular cases. As such, the system is capable of distributing self-contained, interchangeable, modules that can adapt to different situations.

The execution process is also fairly straightforward. At the beginning a Start event is fired-up, prompting to load both a video stream and a tracker. This corresponds to the Tracking and Segmentation Module on the basic architecture (Figure 2). The system chooses between the compatible video inputs and pairs the selection with the proper tracker. This is done by reading the events sent out by the loading functions. Likewise, the model construction rules are loaded after a compatible set of video/tracking inputs has been selected. In this way, we can assure that the modeling algorithm will only take in account pertinent rules, those relying on the specific features we are tracking. This mechanism avoids generating models based on hand positions, for example, if our tracker is only capable of detecting non-manuals. Once a compatible set of modules is activated, the process can continue as proposed by (Curiel and Collet, 2013).

5. Experimental Results
We obtained some preliminary results on the proposed framework by implementing the system’s core and a set of minimal templates for each of the modules on Figure 2. The core contains the necessary data structures to represent both PDL$$_{SL}$$ models and formulae, alongside the semantic rules necessary to acknowledge logical satisfaction.

For the creation of the module templates, we considered two possible scenarios:

- the system is being used to annotate previously captured video corpora;
- a camera as going to be used as input for real-time sign recognition.

Furthermore, we had to consider two distinct cases when treating video; whether we had 2D or 3D information available for determining relationships between hands and body. For simplicity, we worked only with hand-tracking data. Nevertheless, the addition of non-manual trackers is also a possibility, since introducing new modeling rules for non-manuals follow the same principles of the 2D to 3D transition.

Once all the framework tools were in place, we created a specific implementation for the 2D case, when tracking features over existing corpora.

5.1 Automatic Annotation in 2D Corpora
To obtain some initial results over real-world data, we developed the first modules based on the atoms originally presented with the PDL$$_{SL}$$ language. Additionally, we created a property database made of PDL$$_{SL}$$ formulae, adapted to be used with our tracking device. The database position in the architecture is shown in Figure 5, as the node Lexical Formulae. The formulae were exclusively constructed for the 2D case; this means that, for any other kind of tracking information, we would need to define new PDL$$_{SL}$$ database with different properties. For tracking, we used the tracker developed by (Gonzalez and Collet, 2011), which is capable of finding 2D positions of the hands and head over SL video corpora. As for the SL resources, we used an instance of the DictaSign corpus (DictaSign, 2012) as video input for our system.

Since the used tracking tool is not adapted for real-time processing, the implemented tracking module just recuperates
the previously calculated information from an output file. This is done sequentially, after each successful querying of a new video frame, to simulate real-time.

To calculate the posture segmentation we used the method proposed by (Gonzalez and Collet, 2012), which is based on measuring speed-changes.

Our PDL\_SL description database contains four structures:

**opposition.** \( \lambda \text{right} \rightarrow \text{left} \wedge \text{hands} \_\text{config}(c) \). Hands are opposite to each other, with the same configuration.

**tap.** \( \lambda s, w. (\neg T_s^w \rightarrow [\text{moves}(s) \cup \text{moves}(w)]T_s^w \rightarrow [\text{skip}; \text{skip}]\neg T_s^w) \). Hand touches briefly the other hand, only for a single state.

**buoy.** \( \lambda s, \text{posture}. (\text{posture} \wedge [\text{moves}(s)^* \text{posture}) \). The state of one hand remains the same over several states, regardless of the movements of the other hand.

**head anchor.** \( \lambda s, w. \text{posture}, (\text{buoy}(s, \text{posture}) \wedge T_s^\text{head}) \). One of the hands remains within the head region while the other signs.

The \textit{posture} variable denotes the propositional state of an articularator. The \textit{moves(s)} function can be interpreted as any action executed by articularator \( s \). We omit the complete, formal definition of this operator for the sake of readability.

To measure the \textit{hit} ratio of the system, we manually annotated the apparition of the described properties in one video within the corpora. Table 3 shows the quantity of observed apparitions of each property over the chosen video.

| \( \varphi \) | oppos. | buoy | tap | h. anch. |
|-------------|--------|------|-----|---------|
| Total       | 76     | 40   | 33  | 74      |

Table 3: Manually annotated apparitions of property formulae on one video

---

**Figure 5:** Information and control flow in the SL annotation framework
For each signer, the system creates a model based only on the atoms specified by the modeling rules. It then uses the created model to verify every formula on-the-fly. The execution of our algorithm over the same video rendered the results shown in Table 4.

| \( \varphi \) | H. anch. | tap | buoy | opp. |
|-------------|----------|-----|------|------|
| Total       | 138      | 79  | 248  | 164  |

Table 4: Total reported hits of property formulae on one video

On Table 4 we can see the total number of times each of the formulae were verified on the video, as returned by the system. We compare the human annotations with these results on Figure 6.

Figure 6: Formulae verification results

Table 5 shows data from both Tables 3 and 4, alongside a matching table where, for each property formula, we count the quantity of times it was verified on previously human-annotated frames. Each row represents the total number of human observed apparitions of one property, while each column represents the quantity of positive verifications reported by the system for each formula. For example, cell (opposition, opposition) shows the total number of times the opposition formula was correctly verified on human-annotated opposition frames. The next cell, (opposition, buoy), holds the number of times the buoy property was verified on human-annotated buoy frames. Positive verifications can overlap, i.e. the system could have verified two or more formulae over the same states of the model. Therefore, a single annotation could belong to different classes. The cells on the last row of the table correspond to false positives, reported detections that don’t overlap with any human observation.

Further analysis on the matching table is represented on Table 5: Per-formula summary of the total number of observations found, missed and erroneously classified observations.

5.2 Extending to 3D

Currently, we are extending the system to model features tracked in 3D. We have already extended the framework to process data returned by the Kinect (Microsoft, 2013),
a motion sensing device capable of tracking 3D positions on several body articulations. Figure 7 shows the points that can be tracked by using the Kinect with its official development kit.

![Figure 7: Points tracked by the Kinect device (Microsoft, 2013)](Image)

For the moment, we have been able to reuse the same modeling rules that we implemented for the 2D case; mainly, we have used the Kinect tracker to obtain 3D position data of hands and head, and we have projected this information in 2D. This lets us create the same kind of models we build from corpora. However, the variety of the tracked articulations and the 3D capabilities of the sensor, call for the definition of more complex atoms and lambda properties, as well as 3D descriptions of individual signs. As of 2014, work is still ongoing on the matter and has not been properly evaluated. Nevertheless, we considered important to point out that we can already exchange trackers if needed, so as to showcase the flexibility of our framework.

6. Conclusions

Here we have presented an automatic annotation framework for SL based on a formal logic. The system lets us represent SL video inputs as time-ordered LTSs by way of PDL-\textit{SL}, a multi-modal logic. We have shown that it is possible to use the resulting graph to verify the existence of common lexical structures, described as logical formulae. Furthermore, the framework gives us the necessary tools to adapt the model generation for different corpora and tracking technologies.

From the point of view of recognition, we noticed that the quality of the tracking tools is of utmost importance for both formula definition and model generation. The low presence of information and high levels of noise immediately took a toll on verification; in some cases, we lacked enough information to distinguish between intended movements and noise. In turn, this resulted on high rejection rates of what would otherwise be considered hit frames. Similarly, we noticed that modeling can be affected by the presence of low information, which can render states indistinguishable. For instance, without hand configurations every state satisfying \textit{opposition} is, effectively, the same state. Therefore, every formula sharing the same \textit{opposition} base would be satisfied on that single state. This could gravely affect the system’s performance; in the worst case, all states could satisfy all formulae. On the other hand, a too fine-grained model can lead to a LTS that replicates the same problems we have in synthesis-oriented descriptions. In that case, we would need very specific formulae (with near to perfect SL corpora) to achieve any identification at all. Similarly, formula creation can’t be neither too broad nor too specific, if we want to minimize the quantity of imperfect matches. Anyhow, one of the advantages we have by using a logical language is that we can control the granularity of information simply by defining or discarding atoms, which opens the door to the use of algorithmic techniques to control information quantity.

From the point of view of the implementation, the results of the 2D experiments show that further effort has to be put on integrating new sources of information to the system, especially if we want avoid false positives. Even though the system is in place and works as expected, the high quantity of erroneous hits reflects the gravity of the problems we can have with indistinguishable states. Further comparisons have to be done once the system completely incorporates 3D modeling, so as to measure the effective impact of additional information on verification.

Future work in recognition will be centered on implementing machine learning techniques to improve verification. Using data analysis to find relationships between detected structures, could lead us to better results even in suboptimal environments. Additionally, we would like to integrate communication with user level software like the one presented by (Dubot and Collet, 2012), a manual annotation tool. This could lead to other possible uses of the framework as engine for higher applications, such as dictionary searching or even for automatic creation of sign description databases from SL videos.

Further analysis will also target the building blocks of the language, by changing the semantic definitions of PDL-\textit{SL} operators to better suit SL. Changes to its syntax are also to be expected, in an effort to ease the development of extensions for different trackers and simplify descriptions. Finally, we want to steer further into 3D representation and the inclusion of non-manual features, important stepping stones towards higher level language processing.
