Abstract

Chemical abundance of r-process elements in nearby dwarf spheroidal (dSph) galaxies is a powerful tool to probe the site of r-process since their small-mass scale can sort out individual events producing r-process elements. A merger of binary neutron stars is a promising candidate of this site. In faint, or less massive dSph galaxies such as the Draco, a few binary neutron star mergers are expected to have occurred at most over the whole past. We have measured chemical abundances including Eu and Ba of three red giants in the Draco dSph by Subaru/HDS observation. The Eu detection for one star with [Fe/H]=−1.45 confirms a broadly constant [Eu/H] of ∼−1.3 for stars with [Fe/H]≥−2. This feature is shared by other dSphs with similar masses, i.e., the Sculptor and the Carina, and suggests that neutron star merger is the origin of r-process elements in terms of its rarity. In addition, two very metal-poor stars with [Fe/H]=−2.12 and −2.51 are found to exhibit very low Eu abundances such as [Eu/H]<−2 with an implication of a sudden increase of Eu abundance by more than 0.7 dex at [Fe/H]≈−2.2 in the Draco dSph. In addition, the detection of Ba abundances for these stars suggests that the r-process enrichment initiated no later than the time when only a few % of stars in the present-day Draco dSph was formed. Though an identification of the origin of an early Eu production inside the Draco dSph should be awaited until more abundance data of stars with [Fe/H]≤−2 in the Draco as well as other faint dSphs become available, the implied early emergence of Eu production event might be reconciled with the presence of extremely metal-poor stars enriched by r-process elements in the Galactic halo.

Key words: early universe, nucleosynthesis — galaxies: dwarf — galaxies: individual: Draco — Local Group — stars: abundances — stars: Population II

1. Introduction

Neutron star (NS) mergers as the origin of r-process elements have been highlighted thanks to the recent updates from both observational and theoretical studies. First of all, the detection of a bump of a near infrared light in the afterglow of a short-duration γ-ray burst has become compelling evidence for the r-process synthesis in a NS merger event (Barnes & Kasen 2013; Tanvir et al. 2013; Berger et al. 2013; Hotokezaka et al. 2013). Another advancement of our knowledge is brought by the results of theoretical nucleosynthesis calculations; an alternative candidate for the r-process site, neutrino-driven winds of core-collapse supernovae (CCSNe), have been found to become proton-rich due to revised treatments of neutrino transfer and unable to synthesize heavier r-process elements (A>130) (Thompson et al. 2001; Wanajo 2013) while recent studies have shown that NS mergers synthesize and eject them (Korobkin et al. 2012; Bauswein et al. 2013; Wanajo et al. 2014). In addition, chemical feature of r-process elements (Eu and Ba) in the Galaxy can be reproduced by enrichment proceeded through NS mergers in a novel model (Tsujimoto & Shigeyama 2014, hereafter TT14), which improves the mixing process of r-process elements from the previous ones (Mathews & Cowan 1990; Argast et al. 2004) to reflect the kinematic features of ejecta of NS mergers.

TT14 have proposed a more direct assessment of r-process origin by distinguishing between CCSNe and NS mergers from observed chemical abundances in nearby dwarf spheroidal (dSph) galaxies. Since NS merger events are considered to be rare, galaxies with small masses such as faint dSph galaxies are unlikely to leave so many NSs after the deaths of massive stars as to realize their mergers. For instance, a galaxy with its stellar mass of 10^11 M⊙ are expected to host ∼ 500 CCSNe in total assuming a canonical stellar initial mass function (IMF). Then, the estimated frequency of NS mergers of one per 1000-2000 CCSNe (TT14) < 1 NS merger in this galaxy. TT14 examined the observed trend of [Eu/H] against [Fe/H] for three faint dSphs, that is, the Draco, the Carina, the Sculptor, and found a constant [Eu/H] of ∼−1.3 with no apparent increase in the Eu abundance over the metallicity range of −2 < [Fe/H] < −1. This result suggests that the r-process production is associated with events much rarer than SNe, such as NS mergers. On the other hand, bright (i.e., massive) dSphs such as the Fornax and the Sagittarius exhibit a clear increasing [Eu/H] trend with respect to [Fe/H] as in the Milky Way, as might be expected since

† E-mail: taku.tsujimoto@nao.ac.jp
One puzzling question on this dSph matter is why and how these dSph stars are so promptly enriched with r-process elements up to [Eu/H] ∼ −1.3, while these stars claim that no r-process productions operate during a major star formation epoch with [Fe/H] ≥ −2 (see § 4). The idea that the gas forming these galaxies was already enriched at a level of [Eu/H] ∼ −1.3 should be discarded since very metal-poor stars exhibit lower Eu abundance as observed for the star Draco 119 showing [Eu/H] < −2.55 with [Fe/H] = −2.95 (Fulbright et al. 2004). A few stars with [Fe/H] < −3.5 in the Sculptor also exhibit [Eu/H] < −2.2 (Tafelmeyer et al. 2010; Simon et al. 2015). Such low abundances of r-process element is verified by the Ba abundance for very metal-poor ([Fe/H] = −2) dSph stars (Roederer 2013). Therefore it is likely that some kind of r-process synthesis may operate at a very early stage of star formation ([Fe/H] ≤ −2) inside these dSphs and lift Eu abundance up to [Eu/H] ∼ −1.3. Irrespective of its production site, we need to answer how events of r-process synthesis that occurred at a very early stage could leave no trace in stars with [Fe/H] ≥ −2 which constitutes a main body of dSphs.

We aim at making a thorough investigation of the trend of r-process elements imprinted in stars covering the whole metallicity range in faint dSphs by measuring stellar Eu abundance. Note that Eu is an ideal element to trace the r-process enrichment; 97% of the solar Eu abundance was synthesized by r-process, while the fraction of r-process is only 15% in the solar Ba abundance (Burris et al. 2000). In particular, we will focus on (i) confirming a constant [Eu/H] ratio of ∼ −1.3 for [Fe/H] ≥ −2 and (ii) understanding how the [Eu/H] ratio increases up to ∼ −1.3 for [Fe/H] ≥ −2, with a sufficient number of stars in the Draco and the Sextans dSphs.

This first paper presents results of chemical abundances measurements for three red giants in the Draco dSph and discusses their theoretical implications for the origin and enrichment history of r-process elements.

### 2. Observation

Three target red giant stars belonging to the Draco dSph were selected from Kirby et al. (2011). For one of our target stars, Irwin 21275, an upper limit of Eu abundance has been estimated to be [Eu/H] = −1.8 (Cohen & Huang 2009), while no Eu measurements were available for the other two stars.

flat fielding, scattered-light subtraction, and wavelength calibration. The reduced spectra are normalized by fitting the continuum fluxes with polynomial functions. Examples of the reduced spectra of the three program stars together with one comparison star are shown in Figure 1.

### 3. Abundance analysis

We performed a standard abundance analysis using a 1D-LTE analysis code adopted in Aoki et al. (2009), which implements model atmospheres of Castelli & Kurucz (2003). The procedure is briefly summarized as follows (see Ishigaki et al. 2014 for details). First we measure equivalent widths of absorption lines by fitting a Gaussian profile to each absorption feature. The effective temperatures are estimated by \((V-K)\) color and an assumed Fe abundance, using the empirical formula for red giants (Ramírez & Meléndez 2005). The \(log g\) values for the Draco stars are determined using the estimated \(T_{eff}\) by assuming that each star is located on a red giant branch of Yonsei-Yale isochrones (Demarque et al. 2004) with an age 10.9 Gyr (Orban et al. 2008). Then we deduce Fe abundances from the equivalent widths of individual Fe I lines. Here the micro-turbulence velocity parameter (\(\xi\)) is determined so as to meet the condition that Fe abundances deduced from Fe I lines with different excitation energies do not depend on the equivalent widths. With these stellar parameters, we revise the effective temperature and iterate the same procedure until a consistent set of stellar parameters including the Fe abundance is obtained. The results are summarized in Table 2. It should be of note that the estimated parameters for Irwin 21275 agree well with those estimated by Cohen & Huang (2009). The differences between the two analyses are \(\Delta T_{eff} = 90 \, K\), \(\Delta \log g = 0.0\) dex, \(\Delta \xi = 0.1 \, \text{km s}^{-1}\), and \(\Delta [\text{Fe/H}] = 0.1\) dex.

The Eu abundance is estimated by fitting synthetic spectra to each absorption feature. The wavelength region around the Eu II 4129.72 Å line is too noisy for the Draco stars to define a continuum level. Instead we use the Eu II 6645.10 line for the Eu abundance estimate. The local continuum level is defined from the wavelength range of 6649.0-6653.0 Å, in which strong absorption lines are expected to be absent for the stellar parameter range of our target stars. We inspected CN features in the spectra of the three stars, and found that their contribution is negligible in this wavelength range. The modification of the line profile due to the hyperfine structure is taken into account assuming an isotopic fraction for the two naturally existing isotopes, \(^{153}\text{Eu}\) and \(^{155}\text{Eu}\), as \(^{151}\text{Eu}_{i}/(^{151}\text{Eu}+^{153}\text{Eu}) = 0.5\) (Lawler et al. 2001). Results of the fitting are shown in Figure 1. As shown in the two middle panels, the Eu II lines are too weak to be detected for the two stars with [Fe/H] < -2.0 and thus only upper limits are deduced. On the other hand, for one metal-rich star with [Fe/H] > -1.45, the equivalent width due to the Eu II feature is estimated to be 20 mÅ while the 2σ uncertainty estimated from the noise level of the continuum wavelength range is approximately 6 mÅ. Thus we argue that we detected the Eu II line and that its abundance is [Eu/H] = -1.33. The uncertainty in the equivalent width corresponds to an uncertainty in the Eu abundance of no more than 0.15 dex. Changing each of the adopted atmospheric parameters by \(\Delta T_{eff} = \pm 100 \, K\), \(\Delta \log g = \pm 0.3\) dex, and \(\Delta \xi = \pm 0.2 \, \text{km s}^{-1}\) results in \(\Delta [\text{Eu/H}]\) of 0.13 dex at most. The Ba abundances are estimated from the measured equivalent widths of Ba II 5853.69, 6141.73, 6496.91 Å absorption lines. The effect of the hyperfine structure is also taken into account in the same way as in Ishigaki et al. (2013). Results of the abundance measurements are summarized in Table 2. Detailed elemental abundances including \(\alpha\)-, Fe-group, and other neutron-capture elements will be presented in our forthcoming paper (Ishigaki et al., in preparation).

### 4. Eu feature and its implication

In this section, we present the chemical feature of Eu abundance revealed by this study together with previous observations for not only the Draco dSph but also other two dSphs, i.e., the Sculptor and the Carina. Then, we try to advance our knowledge on the enrichment history of r-process elements as
well as their origin. First we show our results for the Draco dSph in Figure 2. The Eu feature can be summarized as (i) the broadly constant Eu abundance of \([\text{Eu/H}] \approx -1.3\) for \([\text{Fe/H}] \approx -2\) and (ii) low Eu abundances of \([\text{Eu/H}] \approx -2\) deviating from a constant value for \([\text{Fe/H}] \approx -2.3\) to \(-2.1\). A majority of stars in the Draco dSph show the first feature, i.e. the constant Eu abundance, because the stellar metallicity distribution function (Kirby et al. 2011) indicates that \(\sim 85\%\) of stars populate the metallicity range of \([\text{Fe/H}] > -2.3\) or \(\sim 70\%\) of stars within \([\text{Fe/H}] > -2.1\). Thus the constant Eu abundance for \([\text{Fe/H}] \approx -2\) suggests a rarity of r-process production events. Using the Kroupa IMF (Kroupa et al. 1993), we obtain the corresponding stellar mass of \(\sim 2.5 \times 10^5 M_\odot\) (Martin et al. 2008) and find that this stellar population presumably hosted \(\sim 1400\) CCSNe in total. Accordingly we conclude that the r-process production did not happen during sequential events of \(\sim 1400\) CCSNe in the Draco dSph. This implied rate is in good agreement with that of NS mergers, one per \(1000 - 2000\) CCSNe, which is deduced from an analysis of chemical abundances in massive dSph galaxies (the Fornax and the Sagittarius) as well as in the Milky Way (TT14).

This broadly constant Eu feature breaks at a very low-metallicity range. Our result for Irwin 20751 indicates a very low \([\text{Eu/H}]\) by more than \(\sim 0.7\) dex at \([\text{Fe/H}] = -2.1 \pm 0.13\) as compared with the plateau abundance of \([\text{Eu/H}] \approx -1.3\). Since the star with \([\text{Fe/H}] = -2.34 \pm 0.19\) (Cohen & Huang 2009) already belongs to the plateau-like Eu abundance branch, \([\text{Eu/H}]\) is likely to have an abrupt change at \([\text{Fe/H}] \approx -2.2\). Other two stars with \([\text{Fe/H}] < -2.5\) exhibiting low Eu abundances clearly confirm the presence of another branch of \([\text{Eu/H}]\) for \([\text{Fe/H}] \approx -2\) far deviating from a constant \([\text{Eu/H}]\) of \(-1.3\). Note that Ba is detected in the spectra of our two stars with \([\text{Fe/H}] < -2\) as well as the star with \([\text{Fe/H}] = -2.95\) (Fullbright et al. 2004). This implies that these stars contain some amount of Eu. Accordingly, from an overall feature of Eu abundance, we conclude that the r-process operates inside the Draco dSph only at an early star formation with its enrichment up to \([\text{Eu/H}] = -1.3\), while a majority of stars formed in the subsequent epoch did not yield r-process elements. Regarding the site of an early Eu production, the feature of a sudden increase in \([\text{Eu/H}]\) by more than \(\sim 0.7\) dex associated with little increase in \([\text{Fe/H}]\) occurring around \([\text{Fe/H}] = -2.2\) seems compatible with the enrichment by a NS merger.

A common feature is shared with the Sculptor and Carina dSphs (Fig. 3). Clearly we see a constant \([\text{Eu/H}]\) for \([\text{Fe/H}] \approx -2\) for the three dSphs. For \([\text{Fe/H}] \approx -2\), the Sculptor dSph also exhibits the low Eu abundance deviating from a constant value by more than \(3\) dex, though the feature of a gradual increase in \([\text{Eu/H}]\) between \([\text{Fe/H}] \approx -2.5\) and \(-2\) is different from that of the Draco dSph. In addition, we present the evolution of \([\text{Ba/Eu}]\) for the three dSphs in Figure 4. We see that dSph stars exhibit a clear increasing trend of \([\text{Ba/Eu}]\), which is considered to be a result of a gradual enrichment of Ba by s-process, though a few stars including our star with \([\text{Fe/H}] = -1.45\) deviate from this trend. Since the observed lower limits of \([\text{Ba/Eu}]\) ratios for the two stars with \([\text{Fe/H}] < -3\) are consistent with a pure r-process Ba/Eu ratio of \([\text{Ba/Eu}] = 0.89\) (Burris et al. 2000), we may be able to guess the values of \([\text{Eu/H}]\) from their Ba abundances. Assuming that these two stars with \([\text{Fe/H}] = -4.05\) and \(-3.52\) hold the pure r-process Ba/Eu ratio, we deduce individual \([\text{Eu/H}]\) abundances of \(-4.57\) and \(-3.14\), respectively. It may give the bottom level of \([\text{Eu/H}]\) abundance in faint dSphs.

Still too small data for \([\text{Fe/H}] \approx -2.5\) cast a veil over the evolutionary path of Eu abundance from the bottom, likely \([\text{Eu/H}] < -3\), to \([\text{Eu/H}] \approx -1.3\) and prevent us from identifying the site of the early Eu production inside faint dSphs. Even if we add information on the Ba feature (Fig. 5), its clear answer continues to elude us. It seems questionable to assume a selective early NS merger which should occur in each of the three dSphs, given its rarity. We may need to introduce some other contributors as an early r-process production such as magnetorotationally driven SNe (Winteler et al. 2012; Wehmeyer et al. 2015). To advance our understanding of the origin of early r-process production, more Eu data with precise measurements for stars with \([\text{Fe/H}] \approx -2\) in faint dSphs together with theo-
retical updates of the models for both NS merger and SNe are surely awaited. In particular, we can raise future prospect that improving the S/N values such as \( \gtrsim 30 \) at the blue wave length of Eu II 4129.7 Å likely achieved by 30m-class telescopes will reveal the Eu feature for very metal-poor regime. Putting aside an enigma on the site of an early Eu production, a clear signature of Eu enrichment imprinted on very early generations of dSph stars is reconciled with the fact that extremely-metal-poor halos stars in the Galaxy are already enriched in r-process, implying little time delay of r-process ejection as compared with other elements such as \( \alpha \)-elements or Fe.

5. Concluding remarks

From an assembly of Eu abundance data thus far obtained for three faint dSph galaxies including our new data for the Draco, it is clear that the trend of [Eu/H] against [Fe/H] shows completely different behaviors between two episodes, i.e., a very early phase and the subsequent major star formation period; a remarkable evolution of [Eu/H] from \(-4\) to \(-1.3\) in the metallicity range of [Fe/H] \(-2\) is followed by broadly constant [Eu/H] until the end of star formation. The latter feature exhibited by a main body of dSph stars that host more than 1000 CCSN occurrences implies an extremely low event of the Eu production. Though NS merger is thought to satisfy this rarity as a source of r-process elements, there exist the Eu production events in the early phase of dSph formation, which remains a mystery. Such an early commencement of r-process enrichment is likely to have something in common with the early r-process enrichment of the Galactic halo.

We are grateful to A. Tajitsu, K. Aoki, and staff members of the Subaru telescope for their helpful support and assistance in our HDS observation. This work was supported by JSPS KAKENHI Grant Number 23224004, 25-7047.
