Abstract

AIM: To derive and validate a score for the prediction of mid-term bleeding events following discharge for myocardial infarction (MI).

METHODS: One thousand and fifty patients admitted for MI and followed for 19.9 ± 6.7 mo were assigned to a derivation cohort. A new risk model, called BLEED-MI, was developed for predicting clinically significant bleeding events during follow-up (primary endpoint) and a composite endpoint of significant hemorrhage plus all-cause mortality (secondary endpoint) incorporating the following variables: age, diabetes mellitus, arterial hypertension, smoking habits, blood urea nitrogen, glomerular filtration rate and hemoglobin at admission, history of stroke, bleeding during hospitalization or previous major bleeding, heart failure during hospitalization and anti-thrombotic therapies prescribed at discharge. The BLEED-MI model was tested for calibration, accuracy and discrimination in the derivation sample and in a new, independent, validation cohort comprising 852 patients admitted at a later date.

RESULTS: The BLEED-MI score showed good calibration in both derivation and validation samples (Hosmer-Lemeshow test P value 0.371 and 0.444, respectively) and high accuracy within each individual patient (Brier score 0.061 and 0.067, respectively). Its discriminative performance in predicting the primary outcome was relatively high (c-statistic of 0.753 ± 0.032 in the derivation cohort and 0.718 ± 0.033 in the validation sample). Incidence of primary/secondary endpoints increased progressively with increasing BLEED-MI scores. In the validation sample, a BLEED-MI score below 2 had a negative predictive value of 98.7% (152/154) for the occurrence of a clinically significant hemorrhagic episode during follow-up and for the composite endpoint of post-discharge hemorrhage plus all-cause mortality. An accurate prediction of bleeding events was shown independently of mortality, as BLEED-MI predicted bleeding with similar efficacy in patients who did not die during follow-up: Area Under the Curve 0.703, Hosmer-Lemeshow test P value 0.547, Brier score 0.060; low-risk (BLEED-MI score 0-3) event rate: 1.2%; intermediate risk (score 4-6) event rate: 5.6%; high risk (score ≥ 7) event rate: 12.5%.

CONCLUSION: A new bedside prediction-scoring model for post-discharge mid-term bleeding has been derived and preliminarily validated. This is the first score designed to predict mid-term hemorrhagic risk in patients discharged following admission for acute MI. This model should be externally validated in larger cohorts of patients before its potential implementation.

Key words: Myocardial infarction; Bleeding; Prediction model; Risk stratification
Core tip: Prediction of mid- to long-term clinically significant bleeding following discharge for a myocardial infarction has received scarce attention from the scientific community. The BLEED-myocardial infarction (MI) prediction model is the first score designed to predict mid-term hemorrhagic risk in these patients. Easy to use and comprising clinical and analytical items that can be collected in a few minutes, BLEED-MI showed good calibration, accuracy and discriminative performance for predicting post-discharge hemorrhagic episodes and a composite endpoint of bleeding events plus all-cause mortality. Importantly, an accurate prediction of bleeding events was shown independently of mortality. Furthermore, a progressively increasing risk of the primary and secondary endpoints was seen with increasing BLEED-MI scores and our results suggested a very high capability of the BLEED-MI rule in identifying low-risk patients. Depending on its potential external validation in larger cohorts of patients, the BLEED-MI score may eventually help tailor therapeutic decisions.

World J Cardiol 2013; 5(6): 196-206 Available from: URL: http://www.wjgnet.com/1949-8462/full/v5/i6/196.htm DOI: http://dx.doi.org/10.4330/wjc.v5.i6.196

INTRODUCTION

Bleeding has emerged as a predictor of early and late mortality in patients with a myocardial infarction (MI)[1-5]. Extensive data indicate that bleeding complications occur with relative frequency (up to 11.4% of patients depending on the type of MI, comorbid illnesses, performance of coronary revascularization procedures or whether patient was given thrombolytic therapy[6-9]), independently affect outcomes, carry similar importance in adversely influencing mortality risk as ischemic events, can be grossly predicted by recognizing patient, presentation, treatment and procedural risk factors for hemorrhagic complications and may be prevented by pharmacologic or non-pharmacologic measures[10].

Despite the proven benefits of anti-platelet or anti-thrombotic drugs, they are mechanistically linked to an increased risk of bleeding. Newer, more potent, agents may increase risk of further ischemic events at a cost of increased bleeding risk, which may decrease compliance[11,12].

A thorough understanding of the prediction of hemorrhagic complications following discharge for acute coronary syndromes is therefore a particularly sensitive concern, as we pursue our common goal of maximizing efficacy of anti-thrombotic drugs while minimizing bleeding risk. Multiple studies have addressed the prediction of bleeding events in the acute/sub-acute phases of a MI or early post-discharge period (30 d within admission) or in patients undergoing percutaneous coronary interven-

tions[7,8,10,13-15]. However, prediction of mid- and long-term hemorrhagic events following an acute coronary syndrome has received surprisingly scare attention from the scientific community. To the best of our knowledge, to this date no risk score has been developed for predicting the mid-term risk of bleeding complications following discharge for a MI. In the context of bleeding assessment, evidence-based decision making should lead to selection of appropriate pharmacologic and nonpharmacologic treatments, invasive or conservative strategies that may offer the best balance of benefit and risk. Furthermore, identification of those patients at highest hemorrhagic risk allows application of more aggressive preventive strategies and potential optimization of outcomes.

The purpose of this investigation was to derive and preliminarily validate a new risk score for the prediction of mid-term bleeding events in patients discharged following admission for a MI.

MATERIALS AND METHODS

Study design

We included all patients admitted at our hospital’s Acute Coronary Care Unit (ACCU) with a diagnosis of MI between December 1, 2006 and August 31, 2009 in a derivation cohort. Using collected baseline data at the time of MI diagnosis and outcome data from this cohort, we developed a new algorithm for the prediction of post-discharge bleeding events-BLEED-MI score. This model was evaluated for its overall predictive performance, discriminatory power and calibration in the derivation sample and in a different cohort comprising patients admitted at our institution for a MI between September 1, 2009 and September 30, 2011.

Patients and eligibility criteria

One thousand and fifty patients consecutively admitted to the ACCU of a tertiary referral hospital and university centre with a MI were included in the derivation sample, while 852 patients admitted at a later date to the ACCU with a MI were assigned to the validation cohort. Eligible patients were required to have a diagnosis of MI according to the Universal Definition of MI[16]. Patients were classified as having acute MI with ST-segment elevation (STEMI) or MI without ST-segment elevation (NSTEMI). Patients with previously known left bundle branch block or ventricular pacemaker rhythm were included in the NSTEMI group.

Data collection

The following data were collected: demographic features, cardiovascular risk factors and previous medical history, physical examination (including weight, height, body mass index, blood pressure and heart rate) and analytical study at admission (including complete blood count, glycaemia, NT-proBNP, C-reactive protein, creatinine, urea, troponin I), maximum troponin I levels, results of coronary angiography and eventual revascularization pro-

| Submitted to revascularization procedures |     |
| 58.60%         | 63.90%            | 0.422   |

NSTEMI: Non-ST elevation myocardial infarction; TIA: Transient ischaemic attack; GFR: Glomerular filtration rate.

Study end points

The primary endpoint of this study was the occurrence of clinically significant bleeding events during follow-up. In-hospital bleeding events were censored, as only post-discharge hemorrhage was considered. Clinical significance of a documented hemorrhage was analyzed according to its severity, localization and associated hemodynamic compromise. Heterogeneous definitions are frequently observed in the trials assessing the benefits of antithrombotic drugs in acute coronary syndromes (ACS), with the Thrombolysis in MI (TIMI) and GUSTO being the two bleeding definitions most commonly used in trials on ACS.\cite{17,18}

Therefore, clinically significant hemorrhage included: (1) major, severe or life-threatening bleeding events, namely those at intracerebral location, those resulting in substantial hemodynamic compromise requiring treatment or in reduction of hemoglobin of 5 g/dL or more (or > 15% in hematocrit); and (2) moderate bleeding, defined by the need for transfusion, a drop in hemoglobin of 3-5 g/dL (or in hematocrit from 10% to 15%) from previous blood tests to the time of admission, the occurrence of spontaneous gross hematuria or hematemesis even in the absence of hemoglobin drop higher than 3 g/dL, or unobserved loss of 4 g/dL or more in hemoglobin.

Minor bleeding, referring to hemorrhagic events not included in the previous categories, nor requiring transfusion or causing hemodynamic compromise or substantial fall in haemoglobin levels, was not assigned to the primary endpoint. Also, blood loss attributable to new revascularization or other surgical procedures was not included.

The secondary endpoint of this study was a composite outcome of post-discharge clinically significant bleeding event plus all-cause mortality.

Patient follow-up

Patients assigned to the derivation cohort were followed for 19.9 ± 6.7 mo following their discharge, while those in the validation sample were followed for a mean period of 13.4 ± 8.1 mo. Follow-up data was obtained from clinical records from outpatient clinic and hospital ward and emergency department admission(s), and through phone calls by the end of a 2-year period after discharge for patients not followed at our hospital.

Statistical analysis

Statistical analysis was done using SPSS, v.17.0. When needed, baseline characteristics are described with mean ± SD for continuous data and counts and proportions for categorical data. The Kolmogorov-Smirnov test was used to test the normal distribution of continuous variables. A model for the prediction of post-discharge mid-term clinically significant bleeding episode was developed in the derivation cohort, comprising several parameters that have been shown before to predict bleeding events in different clinical contexts: age, hemoglobin at admission, GFR by MDRD formula at admission, blood urea nitrogen at admission, history of stroke, bleeding event during hospital stay for the index MI or history of major hemorrhage (defined as non-fatal hemorrhagic stroke or history of serious bleeding requiring transfusion), signs of heart failure before discharge, previously known hypertension, diabetes mellitus, smoking habits and post-discharge treatment with anti-platelet or anticoagulant agents. Gender was indirectly considered, as it is one of the parameters used for the GFR calculation with the MDRD formula. Type of MI, performance of revascularization procedures, implanted stent type per se and atrial fibrillation at admission have not been consistently shown before to predict mid to long-term bleeding events following a MI. Furthermore, as these parameters did not help predict the occurrence of bleeding events during follow-up in univariate analysis, they were not included in our model. Table 1 unveils predictors of clinically significant hemorrhage in univariate analysis and Table 2 illustrates BLEED-MI score calculation.

Patients were divided into three risk categories: (1) BLEED-MI score 0-3: Low risk; (2) BLEED-MI score 4-6: Intermediate risk; and (3) BLEED-MI score ≥ 7: High risk.

In both the derivation and validation cohorts, we assessed the discriminatory power of the BLEED-MI model by calculating the area under each receiver operating characteristic (ROC) curve [area under the curve...

| Yes                                           | 1               |

The BLEED-myocardial infarction (MI) score is obtained by summing all the points assigned for each predictor. Previous neurologic events were defined as history of sudden onset of a focal neurologic deficit in a location consistent with the territory of a major cerebral artery or the radiological documentation of previous cerebral infarction (irrespective of the presence/absence of symptoms); 1Heart failure was defined as a maximum Killip Class > 1 at any time during hospitalization. Therefore, it includes both patients with previous history of heart failure and those with de novo heart failure during hospitalization; 2Including anti-platelet agents (such as Acetylsalicylic Acid and Clopidogrel) and/or anticoagulants (such as Warfarin). At the time patients assigned to the derivation sample were admitted to our Acute Cardiac Care Unit, agents such as Prasugrel, Ticagrelor or Dabigatran were not available; 3History of major hemorrhage defined as previous non-fatal hemorrhagic stroke or history of serious bleeding requiring transfusion. Bleeding event during hospitalization represents the occurrence of a hemorrhagic episode during hospitalization for the MI index, as described for the primary endpoint, plus any significant bleeding event attributable to revascularization procedures (again, as described for the primary endpoint). GFR: Glomerular filtration rate.

(AUC)]. Discrimination, measured in terms of the AUC, refers to BLEED-MI score's ability to assign a higher probability to patients with hemorrhagic events than to those without bleeding episodes. The same analysis was performed for the secondary endpoint, post-discharge all-cause mortality.

Binary logistic regression was performed including the BLEED-MI model exclusively to obtain estimated probabilities of significant bleeding event. Thereafter, the accuracy of the score was analyzed through the Brier score. Accuracy is a measure of the average distance (residual) between the observed outcome and its predicted probability for each individual patient. A popular accuracy measure is the Brier score, which is the squared mean of the residual values. The Brier score is sensitive to both discrimination as well as calibration of the predicted probabilities and describes how well a particular model predicts the likelihood of an outcome in an individual patient (a score of 0.0 implies perfect prediction, while a Brier score of 0.25 suggests lack of utility in endpoint prediction).

The overall tendency of increasing event rates with increasing risk score was tested using chi-square for trend (gamma) and Kaplan-Meier curves were created in the validation sample to evaluate bleeding risk during follow-up and overall event-free survival in each risk category.

Finally, comparison through ROC curve analysis and the integrated discrimination improvement index (IDI) was performed between the BLEED-MI model and the CRUSADE score. The IDI, which may be seen as a continuous form of the net reclassification improvement index, assesses improvement in risk discrimination by estimating the change in the difference in the mean predicted probabilities of the outcome between those with and without the outcome in question. This comparison was performed in the validation sample only.

RESULTS

Baseline characteristics

Table 3 describes both study samples. Of the 1050 patients assigned to the derivation cohort, 91 (8.6%) died during hospitalization, 62 (6.2%) and 200 (21.8%) reached the primary and secondary endpoints during the 19.9 ± 6.7 mo follow-up, respectively. Significant bleeding events occurred in 7.5% (n = 60) of patients included in the validation cohort, while 15.6% (n = 124) reached the secondary outcome during a 13.4 ± 8.1 mo follow-up.

Fifteen point seven percent of patients in the derivation sample were assigned to the low-risk category, while 49.9% and 34.4% were included in the intermediate and high risk strata, respectively. Similarly, 22.9% of patients in the validation sample were assigned to the low risk sub-group, while 39.4% and 37.7% were included in the intermediate and high risk categories, respectively.

Validation of BLEED-MI

Derivation sample: The P value for the Hosmer and Lemeshow goodness-of-fit test confirmed the good calibration of BLEED-MI model (P = 0.371), indicating that the overall model fit was good. Incidence of the primary and secondary endpoints according to risk category is reported on Table 4.

Mean BLEED-MI score in patients reaching the pri-
Incidence of primary and secondary endpoints increased progressively with increasing BLEED-MI scores, as shown in Table 5.

The BLEED-MI score predicted ischaemic events (non-fatal reinfarction and ischaemic stroke) with reasonable, yet lower, discriminative performance (AUC 0.682 ± 0.028, 95%CI: 0.627-0.738, P < 0.001), suggesting a higher utility in the prediction of bleeding. In addition, it was useful in the evaluation of the net clinical risk (composite of death, non-fatal reinfarction, stroke and significant bleeding): AUC 0.760 ± 0.018, 95%CI: 0.724-0.797, P < 0.001.

Validation sample: The Hosmer-Lemeshow test confirmed that there were no statistically significant differences between observed and expected post-discharge hemorrhages across risk groups (P = 0.444).

Incidence of the primary and secondary endpoints according to risk category is reported on Table 6.

Mean BLEED-MI score in patients reaching the primary endpoint was 8.0 ± 2.7 (P = 5.8 ± 2.8 for those without significant hemorrhage, P < 0.001). Brier score analysis using this score demonstrated a mean value of 0.067, suggesting high predictive capacity within each individual patient. BLEED-MI score's discriminatory power was assessed by calculating the AUC for the occurrence of significant hemorrhagic events or the composite endpoint of post-discharge bleeding event plus all-cause mortality: (1) Bleeding event: AUC 0.718 ± 0.033, 95%CI: 0.652-0.783, P < 0.001; and (2) Composite endpoint: AUC 0.774 ± 0.022, 95%CI: 0.731-0.818, P < 0.001.

A BLEED-MI score below 4 had a negative predictive value of 98.9%, for the occurrence of a clinically significant hemorrhagic episode during follow-up and for the composite endpoint of post-discharge hemorrhage plus all-cause mortality.

Incidence of primary and secondary endpoints increased progressively with increasing BLEED-MI scores, as shown in Table 5.

Table 3 Description of derivation and validation samples

| Characteristic                      | Derivation sample (n = 1050) | Validation sample (n = 852) |
|------------------------------------|------------------------------|-----------------------------|

Data are expressed as absolute numbers (percentage) or mean ± SD. TIA: Transient ischaemic attack; BUN: Blood urea nitrogen; CRP: C-reactive protein; NSTEMI: Non-ST elevation myocardial infarction; STEMI: ST elevation myocardial infarction.

primary endpoint was 7.9 ± 2.4 (P = 5.6 ± 2.2 for those without significant hemorrhage, P < 0.001). Brier score analysis using this model demonstrated a mean value of 0.061, which suggests a high predictive capacity within individual patients. BLEED-MI score's discriminatory power was assessed by calculating the AUC for the occurrence of significant hemorrhagic events or the composite endpoint of post-discharge bleeding event plus all-cause mortality: (1) Bleeding event: AUC 0.753 ± 0.032, 95%CI: 0.690-0.816, P < 0.001; and (2) Composite endpoint: AUC 0.808 ± 0.018, 95%CI: 0.772-0.844, P < 0.001.

A BLEED-MI score below 4 had a negative predictive value of 99.2% for the occurrence of a clinically significant hemorrhagic episode during follow-up and for the composite endpoint of post-discharge hemorrhage plus all-cause mortality.
Low-risk (BLEED-MI score 0-3) event rate: 1.2%; intermediate risk (score 4-6) event rate: 5.6%; high risk (score ≥ 7) event rate: 12.5%. In patients who died during follow-up, no clinically significant non-fatal bleeding event occurred in patients assigned to BLEED-MI low and intermediate risk categories, while BLEED-MI high risk patients had a 20.7% bleeding rate.

The BLEED-MI model was superior to the CRU...

### Table 4  Hemorrhagic and combined event rates according to the BLEED-myocardial infarction score risk-group stratification

| Category | Low risk | Intermediate risk | High risk | Gamma for trend | P value |
|----------|----------|-------------------|-----------|----------------|---------|
| Clinically significant bleeding events | | | | | |
| Derivation cohort (follow-up: 19.9 ± 6.7 mo) | Incidence | 0.80% | 3.40% | 14.40% | 0.70 ± 0.08 | < 0.001 |
| Validation cohort (follow-up: 13.4 ± 8.1 mo) | Incidence | 1.30% | 5.00% | 14.10% | 0.61 ± 0.08 | < 0.001 |
| Composite endpoint (bleeding + all-cause mortality) | | | | | |
| Derivation cohort (follow-up: 19.9 ± 6.7 mo) | Incidence | 3.10% | 11.40% | 45.70% | 0.76 ± 0.04 | < 0.001 |
| Validation cohort (follow-up: 13.4 ± 8.1 mo) | Incidence | 1.30% | 9.30% | 31.30% | 0.73 ± 0.05 | < 0.001 |

### Table 5  Primary and secondary endpoint event rates according to the BLEED-myocardial infarction score

| Sample | BLEED-MI score | Bleeding event rate | Composite endpoint event rate |
|--------|----------------|---------------------|------------------------------|
| Derivation sample | 0-1 | 0.80% | 3.10% |
| | 2-3 | 2.70% | 10.00% |
| | 4-5 | 7.90% | 19.10% |
| | 6-7 | 13.60% | 50.40% |
| | 8-9 | 20.00% | 65.90% |
| | 10-11 | 25.00% | 71.40% |
| Gamma for trend | | 0.60 ± 0.07 | 0.70 ± 0.04 |
| P value | < 0.001 | < 0.001 |
| Validation sample | 0-1 | 0.00% | 0.00% |
| | 2-3 | 1.20% | 1.80% |
| | 4-5 | 5.40% | 8.80% |
| | 6-7 | 6.50% | 16.10% |
| | 8-9 | 13.90% | 25.70% |
| | 10-11 | 17.80% | 39.70% |
| | 12-13 | 23.10% | 48.00% |
| | 14-15 | 23.10% | 60.00% |
| Gamma for trend | | 0.52 ± 0.07 | 0.63 ± 0.05 |
| P value | < 0.001 | < 0.001 |

MI: Myocardial infarction.

Figure 1  Kaplan-Meier curves illustrating: A: The occurrence of significant bleeding events during follow-up in the validation sample according to risk-group stratification; B: Event-free survival in the validation sample according to risk-group stratification.

Figure 2  Curvilinear change in expected risk of bleeding with increasing BLEED-myocardial infarction scores (Table 5 illustrates the actual risk of bleeding with increasing BLEED-myocardial infarction scores).
The BLEED-MI score predicted ischaemic events (non-fatal reinfarction and ischaemic stroke) with reasonable, yet lower, discriminative performance (AUC 0.670 ± 0.029, 95% CI: 0.612-0.727, P < 0.001), suggesting a higher utility in the prediction of bleeding, similar to what had been reported in the derivation sample. In addition, it was useful in the evaluation of the net clinical risk (composite of death, non-fatal reinfarction, stroke and significant bleeding): AUC 0.736 ± 0.020, 95% CI: 0.696-0.776, P < 0.001.

**DISCUSSION**

We have derived and preliminarily validate a new bedside prediction-scoring model for clinically significant bleeding events following discharge for acute MI. The score is easy to use and comprises clinical and analytical items that can be collected in a few minutes. The BLEED-MI rule showed good calibration, accuracy and discriminative performance for predicting post-discharge hemorrhagic episodes and a composite endpoint of bleeding events plus all-cause mortality. Importantly, an accurate prediction of bleeding events was shown independently of mortality. Furthermore, a progressively increasing risk of the primary and secondary endpoints was seen with increasing BLEED-MI scores and our results suggested a very high capability of the BLEED-MI rule in identifying low-risk patients, which may be of particular clinical utility.

To the best of our knowledge, this is the first score designed to predict mid-term hemorrhagic risk in patients discharged following admission for acute MI. Other risk scores have been developed to evaluate bleeding risk, but they were designed for patients with atrial fibrillation on oral anticoagulants,[21], for the prediction of inhospital hemorrhages in individuals with ACS[20] or following percutaneous coronary interventions[15], or for stable outpatients with or at risk of atherothrombosis—the REACH score.[22]. The utility and reliability of the REACH score for the prediction of post-discharge bleeding was recently and preliminarily evaluated in a contemporary cohort of patients with acute coronary syndrome. It showed good calibration and reasonable discriminative performance (c-statistic values of 0.65 in the whole population (1548 patients), 0.63 for those without coronary revascularization and 0.67 for those treated with PCI.[23].

All risk factors included in the BLEED-MI score have been demonstrated before to predict hemorrhagic risk in different or similar clinical contexts: (1) Smoking increases the risk of hemorrhagic stroke both in men[24] and women[25], with a graded increase in risk proportional to how many cigarettes are smoked, and is also considered a risk factor for bleeding and perforated peptic ulcers[26]. The REACH risk score, developed for evaluation of the risk of hemorrhagic episodes in stable outpatients with or at risk of atherothrombosis, included “smoking” as one of its variables[22]; (2) A recently published population-based cohort study demonstrated diabetes mellitus was independently associated with an increased risk of major bleeding episodes[27]. The CRUSADE Bleeding score, developed for the prediction of inhosptial major bleeding, incorporates Diabetes[21]. The REACH risk score included diabetes mellitus as well[23]; (3) Age, history of stroke, bleeding history or predisposition and arterial hypertension have been included in the HAS-BLED[7] and HEMORR2HAGES risk scores[21], created for the prediction of bleeding events in patients with atrial fibrillation. Age, hypertension and history of stroke are also among the nine-item REACH risk score[22]; (4) The association between renal dysfunction and bleeding is well documented[7,21,29-31], although a complete understanding of the underlying pathophysiology is still lacking. Impaired platelet function, uremic toxins and anaemia are some of the determinants of uremic bleeding. Renal dysfunction is also a predictor of hemorrhagic episodes in patients with atrial fibrillation, justifying its inclusion in HAS-BLED (defined as the presence of chronic dialysis or renal transplantation or serum creatinine ≥ 200 μmol/L) and HEMORR2HAGES (defined as a creatinine clearance < 30 mL/min)[21] risk scores; and (5) A low baseline haemoglobin level is an independent predictor of the risk of major bleeding in ACS as well as of the risk of death[32]. Some authors have proposed a reverse J-shaped relationship between baseline haemoglobin values and major adverse cardiovascular events[33,34], but whether this J-shaped relationship applies to bleeding events as well is still unknown.

Some risk factors for bleeding previously identified in studies of hospitalized patients were not included in this outpatient score. For example, type of MI (STEMI vs NSTEMI) and anthropometric variables such as weight and body mass index did not help predict hemorrhagic episodes in univariate analysis and were therefore excluded from the model. This decision was substantiated by the lack of studies demonstrating a potential association between the type of MI and mid to long-term hemorrhagic risk and the fact that the inclusion of anthropo-

**Table 6** Number of patients reaching the primary endpoint in the validation sample at different time points

| Time (mo) | Low risk | Intermediate risk | High risk |
|-----------|----------|------------------|-----------|
| 0-3       | 1        | 4                | 21        |
| 4-6       | 0        | 5                | 3         |
| 7-9       | 1        | 4                | 6         |
| 10-12     | 0        | 3                | 4         |
| 13-15     | 0        | 0                | 3         |
| 16-18     | 0        | 0                | 0         |
| 19-21     | 0        | 0                | 1         |
| 22-24     | 0        | 0                | 1         |

SADRE score in the prediction of post-discharge mid-term bleeding events (AUC 7.18 ± 0.033 vs AUC 0.696 ± 0.036, respectively). The IDI and relative IDI were 0.024 and 15.6%, respectively, translating significant improvement in risk classification. BLEED-MI was also more effective in predicting inhospital major hemorrhage when both scores were calculated at admission (AUC 7.19 ± 0.032 vs AUC 0.642 ± 0.038, respectively).

Barra S et al. BLEED-MI: Predicting bleeding events
The moderate size of our derivation and validation samples should be considered the main limitation of this study. In fact, the relatively low absolute number of bleeding events during follow-up (62 in the derivation cohort, 60 in the validation sample) and the low event-per-variable ratio posing the risk of over-fitting[18] reinforces the need for external validation in larger cohorts of patients. However, as no other post-discharge mid-term hemorrhage prediction score has been developed to this date, a comparison between derivation cohorts is not possible.

Another limitation of this investigation concerns the different lengths of follow-up in the derivation (19.9 ± 6.7 mo) and validation (13.4 ± 8.1 mo) samples, which was due to the later admission to our hospital of patients assigned to the validation cohort. This explains why post-discharge mortality rate was slightly higher in the derivation sample compared to the validation cohort. However, this limitation is mitigated by the fact that the majority of hemorrhagic episodes occurred in the first year following the MI index (as expected). Also, as most patients stop dual anti-platelet therapy at the end of the 12th month, their bleeding risk is very likely to decrease. Considering the length of follow-up in the derivation sample was > 1 full year, this limitation did not significantly influence the validation of the model.

An internationally accepted, meaningful and standardized approach for reporting bleeding events is lacking. A fixed definition may not work for all disease states throughout ACS and percutaneous revascularization procedures. Definitions of bleeding overlap to a degree but still differ substantially, which may lead to markedly different conclusions regarding incidence of hemorrhagic episodes, predictors and magnitude of short- and long-term prognostic impact. The clinically important goal of identifying patients at very low or high risk of post-discharge bleeding events increases the need for standardized bleeding definitions. The definition of significant hemorrhagic events used in this study partially overlaps with those of the TIMI[17] and GUSTO[18] trials, but it is unclear whether these definitions remain clinically relevant in the era of routine PCI and aggressive antithrombotic therapy[18]. This should be considered a limitation of the present investigation. Also, our study and model is not yet powered to prediction of clinically significant hemorrhages according to severity (life-threatening vs moderate episodes), due to the overall low number of events in each isolated category.

Recurrent bleeds were not counted and minor bleeding during follow-up was not systematically assessed. This could be viewed as a limitation of the present study, as minor bleeding also affects quality of life and increases health care costs.

A lower rate of revascularization was reported in the derivation group (61% vs 78%), which adds some imbalance to our study populations and may have affected statistical analysis.

Furthermore, although we validated the BLEED-MI score in an independent patient sample and demonstrated
Barra S et al. BLEED-MI: Predicting bleeding events

its overall applicability, internal validation cannot control for unrecognized biases in different institutions. This model should be externally validated in larger cohorts of patients, preferably involving multicentre and prospective registries, before its potential implementation. As external validation requires a second large population for whom all necessary data and long-term outcomes are available, we encourage other institutions to test our score in their populations.

In conclusion, a new risk score for predicting post-discharge mid-term hemorrhagic risk has been derived and preliminarily validated in an independent patient sample. The BLEED-MI model has good calibration, accuracy and discriminatory performance in the prediction of bleeding events or a composite endpoint of bleeding plus all-cause mortality. As it is both easy to use and easy to calculate from routinely available clinical data, it may eventually help clinicians take the most appropriate therapeutic decisions in patients with a MI. Nevertheless, the BLEED-MI score needs external validation in larger cohorts of patients before its potential implementation. We encourage other investigators or institutions to test our model in their patients.
