ABSTRACT

We analyze the time series of Ca II H-line obtained from Hinode/SOT on the solar limb. The time-distance analysis shows that the axis of spicule undergoes quasi-periodic transverse displacement. We determined the period of transverse displacement as $\sim 40 - 150$ s and the mean amplitude as $\sim 0.1 - 0.5$ arc sec. For the oscillation wavelength of $\lambda \sim 1/0.06$ arc sec $\sim 11500$ km, the estimated kink speed is $\sim 13 - 83$ km s$^{-1}$. We obtained the magnetic field strength in spicules as $B_0 = 2 - 12.5$ G and the energy flux as $7 - 227$ J m$^{-2}$ s$^{-1}$.

Subject headings: Sun: spicules · Dynamic parameters
1. Introduction

Spicules can be seen almost everywhere at the solar limb. They are highly-dynamic, thin, jet-like features in the solar chromosphere. Spicules have been observed for a very long time and have been the subject of numerous reviews (Beckers 1968, 1972; Suematsu et al. 1995; Sterling 2000). Perhaps the most interesting aspect about spicules is their potential to mediate the transfer of energy and mass from the photosphere to the corona. This potential has been recognized early (Beckers 1968; Pneuman & Kopf 1978; Athay & Holzer 1982), but the lack of high-quality observations prevented a better understanding of spicules and their link to the corona (Withbroe 1983). The advent of the Hinode Solar Optical Telescope (SOT) (Kosugi et al. 2007; Tsuneta et al. 2008; Suematsu et al. 2008) provided a quantum leap in the understanding of spicules and their properties. With its seeing free high spatial and temporal resolution observations of the chromosphere, Hinode showed much more dynamic spicules than previously thought and re-ignited the discussion on their potential to heat the corona (De Pontieu et al. 2007, 2009, 2011). While there are several recent studies of the properties of spicules using Hinode/SOT (De Pontieu et al. 2007; Anan et al. 2010; Zhang et al. 2012), they are either preliminary results papers or cover only one or two data sets.

It is encouraging that the results from the various groups agree quite well, despite the difficulties in obtaining reliable magnetic field measurements at the limb. Lopez & Casini (2005) used full Stokes polarimetry and Hanle effect modelling of He I D3 spectra and find that the magnetic field strength is mostly 10 G at 3500 km height, with some spicules possibly showing fields up to 40 G. Trujillo et al. (2005) used both the Hanle and Zeeman effects and full Stokes polarimetry of the He I 10830 line and find 10 G at 2000 km and again, some spicules with field strengths up to 40 G. Doppler velocities of solar limb spicules show oscillations with periods of $20 - 55$ and $75 - 110$ s. There is also clear evidence of
3-min oscillations at the observed heights. The observed upwards steady flows are 20 – 25 km s$^{-1}$ with short periods (20 – 55 s) in type I spicules. Type I spicules have typical lifetimes of 150 – 400 s and maximum ascending velocities of 15 – 40 km s$^{-1}$. Type II spicules in the quiet sun have lifetimes between 50 – 150 s, and slightly less in coronal holes. They have a maximum velocity between 40 – 100 km s$^{-1}$, with a very small amount with velocities greater than 150 km s$^{-1}$ (Beckers 1968).

All spicule oscillations events are summarized in a recent review by Zaqarashvili & Erdélyi (2009). They suggested that the observed oscillation periods can be formally divided in two groups: those with shorter periods (<2 min) and those with longer periods (≥2 min) (Zaqarashvili & Erdélyi 2009). The most frequently observed oscillations lie in the period ranges of 3 – 7 min and 50 – 110 s. These spiky dynamic jets are propelled upwards at speeds of about 20 – 25 km s$^{-1}$ from photosphere into the magnetized low atmosphere of the sun. Their diameter varies from spicule to spicule having the values from 400 km to 1500 km. The mean length of classical spicules varies from 5000 km to 9000 km, and their typical life time is 5 – 15 min.

The typical electron density at heights where the spicules are observed is $3.5 \times 10^{-10} – 2 \times 10^{-11}$ kg m$^{-3}$, and their temperatures are estimated 5000 – 8000K (Beckers 1968). Their periods are estimated 20 – 55 and 75 – 110 s. De Pontieu et al. (2007), based on Hinode observations concluded that the most expected periods of transverse oscillations lay between 100 – 500 s, which interpreted as signatures of Alfvén waves. Phase speed begins from ∼ 40 km s$^{-1}$ at lower heights and reaches to the maximum value of ∼ 90 km s$^{-1}$ at ∼ 2500 – 3000 km. Then, it decreases to the minimum value of ∼20 – 25 km s$^{-1}$ at ∼3500 – 4500 km (Ebadi & Khoshrang 2014). Therefore, the observed quasi-periodic displacement of spicule axis can be caused due to fundamental standing mode of kink waves. The energy flux storied in the oscillation is estimated as 150 J m$^{-2}$ s$^{-1}$, which is of the order of coronal
energy losses in quiet Sun regions (Ebadi & Khoshrang 2014). Spicule seismology, which means the determination of spicule properties from observed oscillations and was originally suggested by (Zaqarashvili & Erdélyi 2009), has been significantly developed during last years (Ebadi & Khoshrang 2014; Verth et al. 2011; Ebadi & Ghiassi 2014).

In the present work, we study the observed oscillations in the solar spicules through the data obtained from Hinode. We trace the spicule axis oscillations via time slice diagrams for determining period, amplitude, phase speed, magnetic field, Alfvén speed and energy flux of the studied spicules. Observed waves can be used as a tool for spicule seismology. A description of the observations and image processing is made in Section 2 and in Section 3 we discuss spicules properties. Finally, our conclusions are summarized in Section 4.

2. Observations and data processing

We used a time series of Ca\(\text{II}\) H-line (396.86 nm) obtained on 22 January, 2007, during 23:26 to 23:42 UT by the Solar Optical Telescope onboard (Tsuneta et al. 2008). The spatial resolution reaches 0.2 arc sec (\(\sim\)150 km) and the pixel size is 0.109 arc sec (\(\sim\)80 km) in the Ca\(\text{II}\) H-line. The time series has a cadence of 20 seconds with an exposure time of 0.5 seconds. The position of \(X\text{-center}\) and \(Y\text{-center}\) of slot are 945 arc sec and 0 arc sec, while X-FOV and Y-FOV are 223 arc sec and 112 arc sec, respectively.

The “fgprep”, “fgrigidalign” (available in solarsoft, [http://www.lmsal.com/solarsoft](http://www.lmsal.com/solarsoft)) and “madmax” IDL algorithms are used to reduce the images spikes and jitter effect, to align time series, and to enhance the finest structures, respectively (Shimizu et al. 2008; Koutchmy & Koutchmy 1989).
3. Results and Discussions

In Figure 1, we presented the full view Ca II H-line image of the equator which contains the studied spicules. The processed spicules are indicated by red arrows on this image. This image was taken by Hinode/SOT telescope on 22 Jan, 2007, 23:26:04 UT. We used the time series images of this region and determined period, amplitude, phase speed, magnetic field, Alfvén speed and energy flux of the studied spicules. To this end, we selected 14 random spicules and used time-slice diagrams to illustrate their transversal oscillations.

In Figure 2, we presented the time slice diagrams of the time series which consists of 30 consecutive images. The bright regions show the transversal oscillations of spicules axis. The clear quasi-periodic transverse motion of the spicules axis is seen on the figure. It should be noted that these diagrams are performed at the same height from the limb. In Figure 3, we presented the time slice diagrams and fitted polynomials for three spicules. As it is clear, the fitted functions are the best ones for our observed results. We estimated the oscillation period and amplitude at each diagram and presented them in Table 1.

The density is almost homogeneous along the spicule axis (Beckers 1968); therefore, the density scale height should be much longer than the spicule length. The variation of

| m  | 100           | 0.2            | 27                | 4.2       | 26                |
| n  | 80            | 0.15           | 25                | 5.4       | 14                |
oscillation amplitude with height cannot be due to the decreased density. So, we may have that the oscillation amplitude is proportional to \( \sin(kz) \), where \( k \) is the oscillation wave number. This expression can be approximated in the long wavelength limit as \( \sim kz \). Hence, the oscillation wavelength is \( \lambda \sim 1/0.06 \) arc sec \( \sim 11500 \) km (Ebadi et al. 2012). This allows the estimation of the kink speed as \( v_k \sim 13-83 \) km s\(^{-1}\).

It is possible to estimate the Alfvén speed and consequently magnetic field strength through them. Kink waves are transverse oscillations of magnetic tubes and the phase speed for a straight homogenous tube can be written as:

\[
v_k = \frac{\lambda}{T_{\text{obs}}} = v_A \sqrt{\frac{\rho_0}{\rho_0 + \rho_e}},
\]  

where \( v_A \equiv B_0/\sqrt{\mu_0 \rho_0} \) is the Alfvén speed inside the tube, \( \lambda \) is the wavelength and \( T_{\text{obs}} \) is the observed oscillation period. \( \rho_e \) and \( \rho_0 \) are the plasma density outside and inside of tube, respectively. The density in spicules is \( 3 \times 10^{-10} \) kg m\(^{-3}\) and \( \rho_e/\rho_0 \simeq 0.02 \) (Zaqarashvili & Erdélyi 2009; Ebadi et al. 2012).

The oscillation amplitude and phase speed allows to estimate the energy flux, \( F \), storied in the oscillations:

\[
F = \frac{1}{2} \rho v^2 v_k
\]

where \( \rho \), \( v \) and \( v_k \) are density, wave amplitude and phase speed, respectively (Vranjes et al. 2008). The wave velocity can be determined as \( v = \xi/T_{\text{obs}} \), where \( \xi \) is the axis displacement estimated as \( \sim 0.1 - 0.5 \) arcsec and \( T_{\text{obs}} \) is the oscillation period estimated as \( \sim 40 - 150 \) s. With these parameters the energy flux is estimated as \( F = 7 - 227 \) J m\(^{-2}\) s\(^{-1}\).

Using the kink speed, the magnetic field strength in spicules at the height of 6000 km is estimated as \( B_0 = 2 - 12.5 \) G. This is in good agreement with recently estimated magnetic
field strengths in quiet-Sun spicules (∼10G), which was obtained by spectropolarimetric observations of solar chromosphere in He I λ 10830 (Trujillo et al. 2005; Singh & Dwivedi 2007; Ebadi et al. 2012).

4. Conclusion

We performed the analysis of Ca II H-line time series at the solar limb obtained from Hinode/SOT in order to uncover the oscillations in the solar spicules. We studied 14 random spicules and found that their axis undergo quasi-periodic transverse displacements. The period of the transverse displacements are ∼ 40 – 150 s and the amplitude are ∼ 0.1 – 0.5 arc sec. The same periodicity was found in Doppler shift oscillation by Zaqarashvili & Erdélyi (2009) and De Pontieu et al. (2007), so the periodicity is probably common for spicules. The magnetic field strength in spicules at the height of 6000 km is estimated as $B_0 = 2 – 12.5$ G. These magnetic field strengths are smaller than the values calculated by Zaqarashvili & Erdélyi (2009).

We think that the observed quasi-periodic displacement of spicule axis can be caused due to standing kink waves. The energy flux storied in the oscillations is estimated as $7 – 227$ J m$^{-2}$ s$^{-1}$, which is of the order of coronal energy losses in quiet Sun regions.

Fig. 3.— Time slice diagrams of spicule in Ca II H-line. The blue line is a fit to the oscillation of the spicule.
The authors are grateful to the Hinode Team for providing the observational data. Hinode is a Japanese mission developed and lunched by ISAS/JAXA, with NAOJ as domestic partner and NASA and STFC(UK) as international partners. Image processing Mad-Max program was provided by Prof. O. Koutchmy. This work has been supported financially by the Research Institute for Astronomy and Astrophysics of Maragha (RIAAM), Maragha, Iran.
