Abstract

We consider the Harper model which describes two dimensional Bloch electrons in a magnetic field. For irrational flux through the unit-cell the corresponding energy spectrum is known to be a Cantor set with multifractal properties. In order to relate the maximal and minimal fractal dimension of the spectrum of Harper’s equation to the irrational number involved, we combine a refined version of the Hofstadter rules with results from semiclassical analysis and tunneling in phase space. For quadratic irrationals $\omega$ with continued fraction expansion $\omega = [0; \overline{n}]$ the maximal fractal dimension exhibits oscillatory behavior as a function of $n$, which can be explained by the structure of the renormalization flow. The asymptotic behavior of the minimal fractal dimension is given by $\alpha_{\text{min}} \sim \text{const.} \ln n/n$. As the generalized dimensions can be related to the anomalous diffusion exponents of an initially localized wavepacket, our results imply that the time evolution of high order moments $\langle r^q \rangle$, $q \to \infty$ is sensible to the parity of $n$.

Originally conceived to describe Bloch electrons in a magnetic field \[1\], Harper’s equation

\[ \phi_{n+1} + \phi_{n-1} + 2 \cos(2\pi \omega n + \nu) \phi_n = E \phi_n \]  

has become a subject of its own right. The parameter \( \omega \) is the ratio between the magnetic flux per unit cell and the flux quantum, \( \phi_n \) is related to the wavefunction of the Bloch electron and \( \nu \) is a phase. Harper-like models are of great interest in a wide variety of physical contexts (integer quantum Hall effect \[2\], superconducting networks \[3\], electrons in superlattices \[4\]) and have given rise to strong interplay between physics and mathematics, as e.g. in the fields of semiclassics \[5\], non commutative geometry \[6\], and, quite recently, quantum groups \[7\]. Experimental investigations on superconducting networks permit a direct observation of the ground state energy as a function of the magnetic flux \[8\]. Furthermore, the resolution of the fine structure of Hofstadter’s famous butterfly have been made possible by measuring the magnetoresistance oscillations in superlattices \[8\].

During the last years there has been great interest in the generalized (Rényi) dimensions \[9\] of the spectral measure of this equation and similar quasiperiodic tight-binding hamiltonians \[10–17\]. For the Harper equation it was conjectured that the fractal dimension \( D_{q=0} \) is exactly 1/2 for typical irrational numbers \[15\]. Due to the Thouless property \[19–21\], however, there is a simple argument providing strong evidence for \( D_0 \) being strictly smaller than 1/2 \[22\]. Recently a statistical theory has been presented to explain the numerically observed behavior of \( D_0 \) as a function of the irrational number \( \omega = [0; \pi] \) \[23\]. Until now there is no detailed investigation how the generalized dimensions \( D_q \) for a generic \( q \) depend on the incommensurability \( \omega \). However, the generalized dimensions play an important role for explaining the anomalous diffusion properties of wavepackets found in incommensurable models. Quite recently, the link between \( D_q \) and the anomalous diffusion \( \langle r^q \rangle \sim t^{\sigma_q} \) has been made explicit by the relation \( \sigma_q = D_{1-q} \), which has been verified numerically \[24\].

In this paper we deal with the problem of the maximal and minimal fractal dimensions \( \alpha_{\text{min}} = D_{+\infty} \) and \( \alpha_{\text{max}} = D_{-\infty} \). This is intended to be a first step to general values of \( q \). While \( \alpha_{\text{min}} \) (as \( D_0 \)) exhibits a monotonic behavior as a function of \( n \), we find that \( \alpha_{\text{max}} \) shows strongly pronounced even-odd oscillations that can be explained by a refinement of the Hofstadter rules \[27\]. Similar behavior of \( \alpha_{\text{min}} \) and \( \alpha_{\text{max}} \) has been found for a tight-binding Hamiltonian associated with substitution sequences using the trace map approach \[25,26\].

The paper is organized as follows: We begin by reviewing the Hofstadter rules (1), then we consider the multifractal properties of Harper’s equation for the case of the golden and silver mean (2) and finally pass to more general quadratic irrational numbers (3), where the minimal and maximal fractal dimensions of the related spectrum will be discussed in detail.

**I. HOFSTADTER RULES**

The starting point of our considerations is the hierarchical clustering of the spectrum of Harper’s equation \[1\]. By inspecting the band structure of this equation as a function of \( \omega \), Hofstadter \[27\] noticed that for a given \( \omega \) it consists of three parts, one central cluster (S) and two side clusters (R) that are closely related to the full spectra of Harper’s equation.
with renormalised values of $\omega$, namely $R(\omega)$ and $S(\omega)$ with

$$R(\omega) = \begin{cases} \{\frac{1}{\omega}\} & \text{if } 0 < \omega < \frac{1}{2}, \\ \{\frac{1}{1-\omega}\} & \text{if } \frac{1}{2} < \omega < 1 \end{cases}$$

and

$$S(\omega) = \begin{cases} \{\frac{\omega}{1-2\omega}\} & \text{if } 0 < \omega < \frac{1}{2}, \\ \{\frac{1-\omega}{2\omega-1}\} & \text{if } \frac{1}{2} < \omega < 1 \end{cases}$$

where $\{\cdot\}$ denotes the fractional part (for an illustration see \[27,18\]).

These clustering rules, denoted as Hostadter rules, have been derived afterwards by different methods \[18,29\].

Until now, however, for practical calculations, it has always been assumed that the side clusters and the central cluster are simply rescaled versions of the full spectrum for the renormalized $\omega$. Furthermore only the case of the golden and silver mean ($\omega_{\text{gold}} = [0;\overline{1}]$, $\omega_{\text{silver}} = [0;\overline{2}]$) has been considered. These particular values of $\omega$ are fixed points of both maps, $R$ and $S$, and therefore self-consistent equations for the fractal dimension $D_0$ can be obtained easily \[18\].

In order to refine the assumption that the side and central clusters are merely homogeneously rescaled versions of the full spectrum for the renormalized $\omega$, we rewrite Hofstadter’s clustering rules in a more quantitative way. Consider the spectrum of a rational approximant $\omega = p/q$ with $q$ bands. The partition of these bands on the lower side cluster, the central cluster and the upper side cluster is given according to

$$\text{den }\omega = \text{den }R(\omega) + \text{den }S(\omega) + \text{den }R(\omega),$$

where ”den” denotes the denominator. Therefore we can write the $q$ energy values $E_i$ (upper or lower band edge, for large $q$, in which we are interested, the bandwidths go to zero, so there is no difference) in the following form \[28\]:

$$E_i(\omega) = \begin{cases} f^-_\omega(E_i(R(\omega))) & \text{for } i = 1, \ldots, \text{den }R(\omega) \\ f^+_\omega(E_i-\text{den }R(\omega))(S(\omega)) & \text{for } i = \text{den }R(\omega) + 1, \ldots, \text{den }R(\omega) + \text{den }S(\omega) \\ f^+_\omega(E_i-\text{den }R(\omega)-\text{den }S(\omega))(R(\omega)) & \text{for } i = \text{den }R(\omega) + \text{den }S(\omega) + 1, \ldots, q. \end{cases}$$

The functions $f^{\pm,0}_\omega(E)$ are the fingerprint of Hofstadter’s rules and are essential for calculating the fractal dimensions of the spectrum for a given $\omega$. The irrational number $\omega$ can be developed in a continued fraction. Its truncation at the $k$th level yields the approximant of $\omega$ of generation $k$. An essential point is that $f^{\pm,0}_\omega(E)$ only depend weakly on the generation of the approximant of $\omega$.

For a quasiperiodic tight-binding model where the Hofstadter rules also apply, the functions $f^{\pm,0}_\omega(E)$ have been calculated in a linear approximation by means of a renormalization approach for the case of the golden mean. Since $\omega_{\text{gold}}$ is invariant under $S$ and $R$, the Hofstadter rules close up after the first step, leading to a self-consistent equation for the fractal dimensions \[17\].

A generic quadratic irrational number is not invariant under $R$ and $S$, but successive applications of $R$ and/or $S$ involve a finite number of different irrational numbers. This
can be seen, if the renormalization equations for \( \omega \) are rewritten for the continued fraction expansion \( \omega = [0; a_1, a_2, \cdots] \):

\[
R(\omega) = \begin{cases} 
[0; a_2, a_3, a_4, \cdots] & \text{if } a_1 > 1, \\
[0; a_3, a_4, a_5, \cdots] & \text{if } a_1 = 1
\end{cases}
\]  

(5)

and

\[
S(\omega) = \begin{cases} 
[0; a_1 - 2, a_2, a_3, \cdots] & \text{if } a_1 > 2, \\
[0; a_3, a_4, a_5, \cdots] & \text{if } a_1 = 2, \\
[0; a_2 - 1, a_3, a_4, \cdots] & \text{if } a_1 = 1, a_2 > 1, \\
[0; a_4, a_5, a_6, \cdots] & \text{if } a_1 = 1, a_2 = 1.
\end{cases}
\]  

(6)

Since quadratic numbers have periodic continued fraction expansions, only a finite number of different irrationals will occur by applying iteratively \( R \) and \( S \) to \( \omega \). Thus, once the functions \( f_\omega(E) \) are known for all \( \omega \) involved in the renormalization flow of the initial \( \omega \), the multifractal properties of the spectrum are determined.

We will restrict ourselves to quadratic numbers of the form \( \omega = [0; n] \). Examples of the renormalization flow are given in the following schematic representation for \( n = 3, 4 \):

The structure of these diagrams depends on the parity of \( n \): For \( n \) odd, there are \( n \) irrational numbers involved and \( n + 1 \) cycles occur, \( n \) being of the form \( S^jR \) and one of the form \( S^n \). For \( n \) even, there are \( n/2 \) irrationals and \( n/2 \) cycles occur, \( n/2 - 1 \) of the form \( S^jR \) and one of the form \( S^{n/2} \).

Each of these cycles do only leave invariant the exact irrational number \( \omega \). Applied to an approximant of \( \omega \) of generation \( k \), an approximant of \( \omega \), but of lower generation \( k' < k \) is obtained, as is immediately obvious by inspecting (5) and (6). Thus we can assign to each cycle a ”generation loss” \( d := k - k' \) (cf. Fig. [4]).
II. GOLDEN AND SILVER NUMBER

For the sake of simplicity, we will begin by dealing with the problem for the case \( \omega = \omega_{\text{gold, silver}} \), which are fixed points of the Hofstadter rules. The mapping \( f^{\pm,0}(E) \) has two different fixed points, denoted as \( R \) and \( S \) in Fig. 2, which correspond to the edges respectively to the center of the spectrum. Assuming in a first approximation that the scaling properties of the spectrum are well described by the contraction factors at the centers and at the edges, \( z_S = -\frac{d f^0}{dE}|_{\text{center}} \) and \( z_R = \frac{d f^\pm}{dE}|_{\text{edges}} \), we find that after \( k \) steps of renormalization, the bandwidths scale with \( \Delta \sim z^k \) while the system size scales with \( N \sim \tilde{\omega}^{-k \cdot d} \), where \( \tilde{\omega} \) is the algebraically conjugate to \( \omega \) (\( \tilde{\omega} = \frac{1}{2} \left(n + \sqrt{n^2 + 4}\right) \)) for \( \omega = [0; n] = \frac{1}{2} \left(-n + \sqrt{n^2 + 4}\right) \).

With \( \Delta \sim N^{-1/\alpha} \) we obtain the two local scaling exponents at the edges and the center of the band:

\[
\alpha_S = -\frac{d(S) \ln \tilde{\omega}}{\ln z_S},
\]

and

\[
\alpha_R = -\frac{d(R) \ln \tilde{\omega}}{\ln z_R},
\]

where \( d(S) \) and \( d(R) \) are the generation losses of the cycles \( R \) and \( S \).

Furthermore, within this approximation a self-consistent equation for \( \tau(q) = (q - 1)D_q \), the Legendre transformed of \( f(\alpha) \), can be given directly:

\[
2\omega^{d(R)q} \frac{\omega^{d(S)q}}{z_R^q} + \omega^{d(S)q} = 1, \quad \omega = \omega_{\text{gold, silver}}.
\]

For the case of the golden number, this equation has recently been used to derive the multifractal properties of a tight-binding Hamiltonian associated with the Fibonacci sequence in the limit of strong modulation [16]. Despite of being a good first approximation, the corresponding \( f(\alpha) \) has two serious drawbacks: First, \( f(\alpha_{\text{min}}) \) or \( f(\alpha_{\text{max}}) \) (depending on the parameter) does not vanish in contradiction to numerical simulations and indications from the trace map approach [12]. This problem is due to the oversimplification of \( f^{\pm,0} \) by three linear pieces, yielding an artificial degeneration of the widths of the bands (\( 2^n \) bands of \( \tilde{\omega}^n \) ones have the same widths), which leads to \( f(\alpha_R) \neq 0 \).

Second, in this approach the extremal scaling properties are found at the band edges or at the center of the spectrum. This is, however, by far not the general case. It is true for \( \omega_{\text{gold}} \) for both the Harper model and the quasiperiodic Hamiltonian mentioned above, but neither for \( \omega_{\text{silver}} \), nor for higher irrational numbers \( \omega = [0; \overline{n}], n \geq 3 \).

In order to construct an approach eliminating these two problems, we consider the mapping of the spectrum by the renormalization flow as a discrete dynamical system. For \( \omega_{\text{gold}} \) and \( \omega_{\text{silver}} \) the spectral measure is given by the invariant measure of the map \( f^{\pm,0}(E) \). The band edges and the band center are attracting fixed points of \( f^{\pm,0}(E) \), thus giving rise to nontrivial scaling behavior as we have seen above. To get accurate approximations of the \( f(\alpha) \)-curves, however, we have to take into account higher periodic orbits of the underlying dynamical systems. The simplest approximation is to include the orbit \( R_+ R_- \) of period two.
The energies of the two (symmetric) fixed points are given by \( f^\pm(E) = -E \). Therefore we find for the corresponding scaling factor

\[
\alpha_{R^+R^-} = - \frac{d(R_+R_-) \ln \tilde{\omega}}{\ln z_{R^+} + \ln z_{R^-}} = - \frac{d(R) \ln \tilde{\omega}}{\ln z_{R^\pm}},
\]

(10)

where \( z_{R^\pm} \) is the local contraction factor at the fixed points of order two:

\[
z_{R^\pm} = \frac{df^{\pm,0}(E)}{dE} \bigg|_{E=-f^\pm(E)}.
\]

(11)

Taking into account the three contraction factors \( z_R, z_S, z_{R^\pm} \) (denoted as 3\( z \)-model in the following) we arrive at the following self-consistent equation for \( \tau(q) \):

\[
\frac{\omega d(R)q}{z_R} + \frac{\omega d(R)q}{z_{R^\pm}} + \frac{\omega d(S)q}{z_S} = 1, \quad \omega = \omega_{\text{gold}}, \omega_{\text{silver}}.
\]

(12)

If \( z_{R^\pm} \) equals \( z_R \) equation (12) reduces to (9).

The minimal and maximal dimensions for the 3\( z \)-model are given by \( \alpha_{\text{min(max)}} = \min(\max)\{\alpha_R, \alpha_S, \alpha_{R^\pm}\} \). By performing the Legendre transformation of (12) we find the correct behavior \( f(\alpha_{\text{min(max)}}) = 0 \). While for the golden number \( \alpha_{\text{max}} = \alpha_S > \alpha_{R^\pm} > \alpha_R = \alpha_{\text{min}} \), i.e. the maximal scaling exponent occurs at the center of the spectrum, for the silver number the maximal dimension is given by \( \alpha_{\text{max}} = \alpha_{R^\pm} > \alpha_S > \alpha_R = \alpha_{\text{min}} \), i.e. the bands of maximal widths are not at the center of the spectrum, but at the energy given by \( f^\pm(E) = -E \). Therefore a linear approximation of \( f^{\pm,0}(E) \) (i.e. two scaling factors, one for the central, and one for the side bands) is not sufficient for explaining \( \alpha_{\text{min}} \) and \( \alpha_{\text{max}} \), even in the case of \( \omega_{\text{silver}} \).

The approximative \( f(\alpha) \)-curves calculated from equation (12) are compared in Fig. 4 with those obtained by the usual multifractal formalism [9]. Despite of the simplicity of our model there is a good agreement between the curves. Including linearization around further periodic orbits of the non-linear map \( f^{\pm,0}(E) \) would yield further quantitative improvement. We consider the 3\( z \)-model as the simplest qualitatively correct approximation.

Let us note that the Thouless property \( D_{-1} = 1/2 \) (i.e. \( \tau(-1) = -1 \)) yields one linear equation which the three contraction factors have to fulfill:

\[
\frac{z_R}{\omega d(R)} + \frac{z_{R^\pm}}{\omega d(R)} + \frac{z_S}{\omega d(S)} = 1, \quad \omega = \omega_{\text{gold}}, \omega_{\text{silver}}
\]

(13)

Thus, by use of this relation, the calculation of the scaling behavior at the band-edges \( z_R \) and at the center of the band \( z_S \) would enable to obtain the missing contraction factor \( z_{R^\pm} \).

### III. HIGHER QUADRATIC IRRATIONAL NUMBERS

Hitherto we have been considering the case of the fixed points of the Hofstadter rules, where the renormalization always yields the same function \( f^{\pm,0}(E) = f^{\pm,0}_{R^0}(E) = f^{\pm,0}_{S^0}(E) \) that can be considered as a dynamical system. We have shown that taking into account not only the fixed points of this dynamical system, but also a periodic orbit of length two,
satisfactory $f(\alpha)$-curves can be obtained. Now we generalize this approach to the irrational numbers $[0; \pi]$ that are not fixed points of the Hofstadter rules but give rise to a nontrivial cycle structure that has been shown above.

In this case we have to deal not only with one function $f_\omega^\pm(0)$ but with a whole set of functions \( \{f_\omega^\pm(E)\} \), where the \( \omega_i \) are the irrational numbers occuring in the flow diagram of \( \omega \). In order to calculate the scaling properties of the spectrum, we have to consider the cycles of the flow diagram. To each cycle there is one effective \( f_\omega^\pm(0) \) that results from concatenating the corresponding maps \( f_\omega^\pm(E_i) \) for the \( \omega_i \) occuring in this cycle. For example, the effective map of the cycle \( S^2R \) in the case of \( \omega = [0; 3] \) is given by \( f_\omega^\pm = f_0^{\pm} \circ f_0^{\pm} \circ f_{[0;3]}^{\pm} \) (consider equation (4) and the flow diagram). Each of these effective maps can be considered as a dynamical system with fixed points and periodic orbits of different lengths.

Now two natural questions arise: Which cycle of the renormalization flow does lead to the minimal (respectively maximal) local scaling exponent? Which fixed point or periodic orbit of the dynamical system corresponding to this cycle does yield the extremal scaling exponent? In a first step, these two questions can be addressed numerically by determining the index of the band of maximal (respectively minimal) width and following its way under the renormalization flow.

We find that the the minimal scaling exponent for \( \omega = [0; \pi] \) occurs for the cycle \( R \) (these \( \omega \) are fixed points of \( R \)), i.e. the smallest bands occur at the edges of the spectrum. More interestingly, the maximal scaling exponent occurs for the cycle \( S^{n-1}R \) (\( n \) odd) respectively for \( S^{n+1}R \) (\( n \) even). The lengths and the structure of these cycles show a striking even-odd effect which is a direct result of the Hofstadter rules. Furthermore, for \( n \) odd the maximal scaling exponent is given by the fixed point of the effective dynamical system, while for even values of \( n \) the asymmetric orbit of length two yields the maximal scaling exponent.

For the minimal exponent we find for \( \omega = [0; \pi] \):

\[
\alpha_{\min} = -\frac{\ln \bar{\omega}}{\ln z_R([0; \pi])},
\]

and for the maximal exponent we obtain

\[
\alpha_{\max} = -\frac{2 \ln \bar{\omega}}{\ln |f'_\omega(E_1^*)|} \quad \text{if } n \text{ odd},
\]

\[
\alpha_{\max} = -\frac{\ln \bar{\omega}}{\ln |f'_\omega(E_2^*)|} \quad \text{if } n \text{ even},
\]

where \( E_1^* \) (\( E_2^* \)) is the energy of the fixed point (energy of the orbit of period two) of the effective map \( f_\omega^\pm(E) \). Replacing the effective map \( f_\omega^\pm(E) \) by the individual maps, we find

\[
\alpha_{\max} = -\frac{2 \ln \bar{\omega}}{\sum_{i=1, i \neq 2}^n \ln z_S([0; i, \pi]) + \ln z_R([0; 2, \pi])} \quad \text{if } n \text{ odd}
\]

\[
\alpha_{\max} = -\frac{\ln \bar{\omega}}{\sum_{i=4, i \text{ even}}^n \ln z_S([0; i, \pi]) + \ln z_R^{\pm}([0; 2, \pi])} \quad \text{if } n \text{ even}.
\]

Inspecting these two equations one is lead to the assumption that \( \alpha_{\max} \) as a function of \( \omega = [0; \pi] \) should be sensible to the parity of \( n \), while \( \alpha_{\min} \) is expected to show a monotonic
behavior as a function of \( n \). This is indeed the case, as shows Fig. [F]. For a more quantitative discussion of our approximation, however, the behavior of \( z_R, z_{R\pm} \) and \( z_S \) as a function of \( \omega \) is required. For limiting cases, as \( \omega \to 0 \) or \( \omega \to \frac{1}{2} \), the contraction factor \( z_S \) can be obtained by semiclassical analysis and by considering tunneling in phase space [23,30,31,32,33], if one makes the further assumption that \( f^0(E) \) is nearly linear, so that \( z_S \) can be written as ratio of band edges: \( z_S(\omega) = E_{1-}(\omega)/E_0(S(\omega)) \). For \( \omega \to 0 \) \( z_S(\omega) \) is therefore given by the ratio of two Landau levels and with the results of [F] we find:

\[
z_S(\omega) = 1 - \pi \omega + \pi \omega^2 + (2\pi - \pi^2 + \frac{\pi^3}{24})\omega^3 + \mathcal{O}(\omega^4) \quad (\omega \to 0).
\]  

(19)

For \( \omega \to \frac{1}{2} \) tunneling has to be taken into account for determining \( E_{1-}(\omega) \) and we find

\[-\frac{1}{\ln z_S(\omega)} \simeq b_S(\frac{1}{2} - \omega) + c_S(\frac{1}{2} - \omega)^2 + d_S(\frac{1}{2} - \omega)^2\ln(\frac{1}{2} - \omega) \quad (\omega \to \frac{1}{2}),\]

(20)

where \( b_S \) is given analytically by \( b_S = \pi \cdot (\int_0^{\pi/2} \ln(\cos k + \sqrt{1 + \cos^2 k})dk)^{-1} \approx 3.429815 \) and \( c_S \) and \( d_S \) are fit parameters (cf. appendix). Although equations (19) and (20) are only expansions near \( \omega = 0 \) and \( \omega = \frac{1}{2} \), they describe \( z_S(\omega) \) over the whole range \( 0 < \omega < \frac{1}{2} \) amazingly well, if one takes equation (19) for \( 0 < \omega < 0.25 \) and equation (20) for \( 0.25 < \omega < 0.5 \) (cf. Fig. [F]).

In principle, a similar analysis can be performed for the mean slope \( \overline{\omega_R} = (E_0(\omega) - E_{1+}(\omega))/(2E_0(R(\omega))) \). As the linear approximation for \( f^\pm(E) \) assumed in this relation is a rather crude one for general \( \omega \), the values of \( z_R \) and \( z_{R\pm} \) can deviate considerably from \( \overline{\omega_R} \). This, however, is not the case for \( \omega \to 0 \), where \( z_R \) and \( z_{R\pm} \) are well approximated by \( \overline{\omega_R} \) that is given in this regime by

\[-\frac{1}{\ln \overline{\omega_R}(\omega)} = b_R\omega + c_R\omega^2 + d_R\omega^2\ln\omega, \quad (\omega \to 0)\]

(21)

where \( b_R = 2\pi \cdot (\int_0^{2\pi} \ln(2 - \cos k + \sqrt{(2 - \cos k)^2 - 1})dk)^{-1} \approx 0.857454 \) and \( c_R \approx 1.5 \) and \( d_R \approx 0.37 \) again are fit parameters.

As \( \alpha_{\min} \) is determined by \( z_R[0; \overline{n}] \approx \overline{\omega_R}[0; \overline{n}] \) (as \([0; \overline{n}] \to 0 \) for \( n \to \infty \)), we insert equation (21) into (14) and obtain

\[\alpha_{\min} \simeq (b_R\omega + c_R\omega^2 + d_R\omega^2\ln\omega)\ln\overline{\omega},\]

(22)

where \( \omega = \frac{1}{2}(\sqrt{n^2 + 4} - n) \) and \( \overline{\omega} = \frac{1}{2}(n + \sqrt{n^2 + 4}) \). Therefore, asymptotically \( \alpha_{\min} \sim b_R \ln n/n \quad (n \to \infty) \) and \( \lim_{n \to \infty} \alpha_{\min} = 0 \).

For \( \alpha_{\max} \) the values \( z_R \) and \( z_{R\pm} \) for \( \omega \) near to \( \frac{1}{2} \) are needed. As they are not directly available in our approach, we take approximately \( z_R(\omega) = \overline{\omega_R}(\omega) \) and \( z_{R\pm} = 1.4\overline{\omega_R}(\omega) \), where \( \overline{\omega_R}(\omega) \) is given by equation (21). This approximation is intended to give the qualitative behavior for \( \alpha_{\max} \).

In Fig. [F] the predictions for \( \alpha_{\min} \) and \( \alpha_{\max} \) for \( 3 \leq n \leq 10 \) are compared with the corresponding values obtained by diagonalization. For \( \alpha_{\min} \) and \( n \geq 5 \) there is good agreement between prediction and simulation, while for \( n < 5 \) the predicted value of \( \alpha_{\min} \) are to high, reflecting the fact that \( z_R < \overline{\omega_R} \). For \( \alpha_{\max} \) we find qualitatively the even-odd oscillations, but
of course, due to the problems mentioned above, we can not hope to achieve quantitative agreement. In particular an open question is the behavior of $\alpha_{\text{max}}$ for $n \to \infty$. For the moment, we can only state, that if $\ln z_R(\omega)$ and $\ln z_{R\pm}(\omega)$ is bounded for $\omega \to \frac{1}{2}$, then $\alpha_{\text{max}}$ does not reach the value 1 for $n \to \infty$.

Summing up, we have used a refined version of Hofstadter rules together with results from semiclassical analysis to link the maximal and minimal fractal dimension of the spectrum of the Harper equation to the continued-fraction expansion of the irrational number characterizing the flux per unit-cell. We have shown that the oscillatory behavior of $\alpha_{\text{max}}$ for $\omega = [0; n]$ as a function of $n$ can be qualitatively explained by the discrete flow diagrams of the Hofstadter rules. For $\alpha_{\text{min}}$ an explicit expression has been given which describes fairly well the data obtained by diagonalization. We conjecture that the result for $\alpha_{\text{max}}$ can be generalized to quadratic numbers of the continued fraction expansion $\omega = [0; n_1, n_2, \cdots, n_p]$. Take for example $\omega = [0; n_1 n_2]$. In this case the renormalization flow diagram contains $\frac{1}{2}(n_1 + n_2)$ different irrational numbers, if both $n_1$ and $n_2$ are even. In all the other cases, there are $n_1 + n_2$ different irrational numbers. Thus for even values of $n_1$ the cycle structure depends on the parity of $n_2$, while this is not the case for $n_1$ odd. Hence, for fixed even values of $n_1$ we expect even-odd oscillations of $\alpha_{\text{max}}$ as function of $n_2$, while for odd values of $n_1$ no such oscillations are expected.

Finally we note that the applicability of the Hofstadter rules to a wide class of quasiperiodic models suggests that our method could be useful for other models than the one we have considered here.

IV. APPENDIX

This appendix is intended to provide the calculations for $z_S$ and $z_R$ in the semiclassical approximation using methods and results described in \[30,31] 33.

Equation (19) can be obtained directly by inserting the semiclassical expansion of the Landau levels up to order three \[5\] into

$$ z_S(\omega) = \frac{E_{1-}(\omega)}{E_0(\frac{\omega}{1-\omega})}, \quad (\omega \to 0). \quad (23) $$

For $\omega \to \frac{1}{2}$ the contraction factor $z_S$ is given by

$$ z_S(\omega) = \frac{E_{1-}(\omega)}{E_0(4(\frac{1}{2} - \omega))}, \quad (\omega \to \frac{1}{2}). \quad (24) $$

While the denominator corresponds to Landau levels near $\omega = 0$ and the already mentioned semiclassical expansion can be used, the numerator involves the calculation of $E_{1-}(\omega)$ for $\omega \to \frac{1}{2}$. Since for $\omega = \frac{1}{2}$ the effective Hamiltonian $H = \pm 2\sqrt{\cos^2 k_1 + \cos^2 k_2}$ has the form of a Dirac operator at the four critical points $(\pm \frac{\pi}{2}, \pm \frac{\pi}{2})$ (independent signs) \[5\], we are left with the calculation of tunneling between Dirac levels.

Although the usual formula for level splitting due to tunneling

$$ \Delta E \sim \text{const} \cdot \hbar \cdot \exp \left( -\frac{|\text{Im}S|}{\hbar} \right), \quad (25) $$

where \( S \) is the action integral between degenerate minima, \( \hbar \) is Planck’s constant and the proportional constant is related to the classical frequency, was originally derived for tunneling between parabolic minima \([34]\), we tentatively use it for our case, where the minima are conical. With \( \hbar = 2\pi(\frac{1}{2} - \omega) \) \([3]\) we obtain

\[
E_{1-}(\omega) \sim (1/2 - \omega) \exp \left( -\frac{|\text{Im}S|}{2\pi(1/2 - \omega)} \right),
\]

where the action integral has to be calculated between two adjacent minima in phase space. The (complex) orbits are given by \( H = 0 \), i.e. \( \cos^2 k_1 + \cos^2 k_2 = 0 \) and therefore

\[
S = \int_{-\pi/2}^{\pi/2} \arccos(\pm i \cos k_1) \, dk_1
\]

\[
|\text{Im}S| = 2 \int_0^{\pi/2} \ln(\cos k_1 + \sqrt{1 + \cos^2 k_1}) \, dk_1 \approx 1.831931.
\]

Formula (26) with (28) inserted is compared to numerical results from diagonalisation in Fig. 7. We note that the fact of the action being purely imaginary shows the absence of braiding of the Dirac levels. To calculate \( z_S(\omega \to 1/2) \) we insert (26) together with

\[
E_0(4(1/2 - \omega)) \sim 4 - 8\pi(1/2 - \omega) + \mathcal{O}((1/2 - \omega)^2)
\]

into (24) and obtain (20). The parameters \( c_S \approx 9.6 \) and \( d_S \approx 5.2 \) are determined by fitting to the numerical data.

The calculations for \( z_R(\omega \to 0) \) are analogous, but only Landau levels have to be considered.

FIG. 1. Cycles occurring in the discrete renormalization diagram for $\omega = [0; \pi]$.  

FIG. 2. Schematic representation of $f^{\pm,0}(E)$. The points $R$ and $S$ are the fixed points of $f^{\pm,0}(E)$. The point $R_\pm$ corresponds to the two-orbit $E \to -E \to E$.  

12
FIG. 3. One quarter of the Hofstadter’s butterfly. The band edges $E_0(\omega)$, $E_{1+}(\omega)$ and $E_{1-}(\omega)$ are depicted with lines.
FIG. 4. The multifractal spectrum $f(\alpha)$ for the Harper model for $\omega_{\text{gold}}$ (narrow curve) and $\omega_{\text{silver}}$ (large curve) compared to the 3z-model. The $f(\alpha)$-curves obtained from diagonalization and the thermodynamic formalism are drawn with symbols, the $f(\alpha)$ obtained from Legendre-Transformation of (12) are depicted with lines ($z_{R_{\text{gold}}}^{\text{gold}} = 0.103$, $z_{R_{\parallel}}^{\text{gold}} = 0.164$, $z_{S}^{\text{gold}} = 0.0718$; $z_{R_{\text{silver}}}^{\text{silver}} = 0.118$, $z_{R_{\parallel}}^{\text{silver}} = 0.248$, $z_{S}^{\text{silver}} = 0.020$).
FIG. 5. The contraction factor \( z_S(\omega) = E_{1-}(\omega)/E_0(\omega) \) compared to the results from semiclassical analysis (equation (19) for \( 0 < \omega < 0.25 \) and equation (20) for \( 0.25 < \omega < 0.5 \) \( b_S = 3.429815, c_S = 9.6, d_S = 5.2 \)). Note that \( z_S(\omega) \) is remarkably smooth compared to \( E_{1-}(\omega) \) and \( E_0(\omega) \) (Fig. 3).
FIG. 6. The fractal dimensions $D_{-\infty} = \alpha_{\text{max}}$ and $D_{\infty} = \alpha_{\text{min}}$ for $\omega = [0; \pi]$ as a function of $n$. Results of diagonalization are depicted with points, the lines refer to equation (22) and (18).
FIG. 7. The broadening of the Dirac level at $E = 0$, $\omega = \frac{1}{2}$ compared to the result from tunneling in phase space $-1/\ln E_1(\omega) \sim 2\pi(\frac{1}{2} - \omega)/|\text{Im}S|$, where the imaginary part of the action is given by $|\text{Im}S| = \int_{-\pi/2}^{\pi/2} \ln(\cos k + \sqrt{1 + \cos^2 k})dk \approx 1.831931$. For $1/2 - \omega < 0.013$ the broadening of Dirac levels can not be resolved numerically.
